### Biographies

**Atif N Qasim** is an assistant professor in the Division of Cardiology at the University of California, San Francisco (UCSF). He earned his MS/BS in Biochemistry and Biophysics at Yale University and completed medical school at the Johns Hopkins University School of Medicine. After residency and chief residency in Internal Medicine at the Hospital of the University of Pennsylvania, he completed his clinical cardiology training with a specialization in non-invasive imaging at the same institution. There he also completed a master's degree in clinical epidemiology. The focus of his research is the use of non-invasive imaging for the prevention of cardiovascular disorders.

Dr Qasim is the author of several peer-reviewed manuscripts in this area. Along with Dr Muredach Reilly, he co-authored the previous edition of the chapter on the Genetics of Atherosclerosis in this textbook. He has written a handbook of medicine for medical students and residents, *The Hitchhiker's Guide to Internal Medicine*, and is the author of several chapters in cardiology texts relating to non-invasive imaging and general cardiology. He is also the founder of CardioQnA, a company which centers on medical education, as well as the website [www.echocardiographer.org](http://www.echocardiographer.org), a learning resource and image library for echocardiography.

**Muredach P Reilly** is an associate professor of Medicine and Pharmacology in the Perelman School of Medicine at the University of Pennsylvania (Penn). He earned his medical degree at University College Dublin, Ireland and completed training in medicine and cardiology as well as epidemiology at Penn. He leads a translational cardio-metabolic research program at Penn with specific focus on unbiased genomic discovery approaches, including GWAS, to CHD traits and functional studies of newly identified loci for CHD. His clinical specialty is in Preventive Cardiology and oversight of acute coronary care. He maintains multiple NIH awards for his cardio-metabolic research program and has published over 100 peer-reviewed research articles as well as many articles relating to genomics of CHD and its metabolic risk factors.

### 56.1 INTRODUCTION

The vasculature is the first organ system to develop during embryogenesis, delivering nutrients, growth factors, and oxygen to tissues and removing waste products. It is therefore essential for development. The vascular system comprises four major compartments (arterial, capillary, and venous blood vessels, and lymphatic vessels), which have in common the presence of endothelial cells (ECs) forming the innermost layer. In blood vessels, the endothelial tubes are supported by a layer of vascular smooth muscle cells (vSMCs) and/or pericytes (together called mural cells) of variable thickness, whereas only a few SMCs are present in certain areas of large lymphatic vessels.

The mechanisms that give rise to the mature vascular network are complex. These developmental processes, termed vasculogenesis, angiogenesis, and lymphangiogenesis, involve a plethora of signaling molecules and their receptors at various time-points. The best known are the angiopoietins (ANGPTs), ephrins, fibroblast growth factors, platelet-derived growth factor, transforming growth factor beta (TGF $\beta$ ), and vascular endothelial growth factors. As suggested by numerous murine models showing abnormal vascular development, many other factors, including those participating in cell–cell and cell–matrix interactions, are probably also involved.

Vascular anomalies result from localized defects that occur during vascular development (1,2). They are subdivided into vascular tumors (mainly hemangiomas) and vascular malformations, which in turn are subcategorized according to the type(s) of vessel(s) altered (3,4).

Thus, capillary, venous, arteriovenous, lymphatic, and combined malformations can be distinguished.

### 56.2 THE VENOUS SYSTEM

Veins collect blood from the capillary network and contain about 75–80 % of the total volume of blood in the body. These vessels are larger than arteries, but their walls consist of a thinner layer of vSMCs and a thicker adventitia. The presence of valves allows for proper orientation of blood flow in veins. Venous flow is passive, essentially mediated by physical movements of the body and the aspirating effect exerted by the heart. Some veins, especially in the legs, are exposed to high pressure due to gravitational forces and subject to permanent distortions (i.e. varicose veins).

During vascular development, a primary capillary plexus is formed early on by in situ differentiation of hemangioblasts, originating from the mesoderm, into ECs that assemble to form endothelial tubes (vasculogenesis). In response to the hemodynamic forces of local blood flow, this plexus is progressively remodeled during angiogenesis to form the three types of blood vessels. At the cellular level, the “venous” phenotype of the ECs is determined very early, even before the vessel is committed to a vein (5). In the trunk of the embryo, the venous system is first present as symmetrical bilateral vessels. Then, the left part regresses progressively while the right-sided veins evolve into the superior and inferior vena cava. Defective remodeling may lead to retention of embryonic veins, such as persistence of the left superior vena cava (6,7), or the right umbilical vein (8).

Among abnormalities of the veins, a persistent saphenous vein is sometimes observed in Klippel–Trenaunay patients (9).

## 56.3 DISORDERS OF THE VENOUS SYSTEM

Venous malformations (VM), the main focus of this chapter, are the most frequent malformations seen in interdisciplinary vascular anomaly centers. Varicose veins and varicosities are discussed with the disorders affecting lymphatic vessels (Chapter 50). Malformations with capillary or arteriovenous components are described in Chapter 57. Neither will we discuss the diagnostics and management of acute and chronic venous disorders, which have been extensively reviewed elsewhere (10).

### 56.3.1 Glomuvenous Malformation

The most frequent inherited VM, glomuvenous malformation (GVM; Online Mendelian Inheritance in Man (OMIM) 138000) accounts for roughly 5% of venous malformations (VMs) (11), and is often improperly called “glomangioma” or “(multiple) glomus tumor” although it is not a tumor and never becomes malignant. GVM is characterized by the presence of a variable number of “glomus cells” around distended venous channels (12,13). Similar rounded cells are present in paraganglioma (OMIM 115310, 168000, and 605373) and (subungual) solitary glomus tumor. All are sometimes referred to as “glomus tumor.” However, paragangliomas are tumors of the parasympathetic ganglia, most commonly located in the head and neck area, caused by mutations in three different subunits of the succinate dehydrogenase enzyme complex, namely SDH-B, SDH-C, and SDH-D, and more rarely in SDHAF2 (14–19). Solitary glomus tumors are usually subungual painful lesions histologically characterized by the presence of glomus cells, but without important vascular component (20).

GVM segregates as an autosomal dominant disease, with incomplete penetrance and variable expressivity (13,21–24). Frequently, a single individual in a family is more severely affected and is brought to the medical attention, whereas most of the other affected individuals have small lesions and never consider treatment (25). As penetrance is below 100% and many individuals have tiny asymptomatic lesions, it is likely that the inherited nature of patients’ lesions is overlooked.

Clinical distinction of GVM from VMs and multiple cutaneous and mucosal venous malformations (VMCM) can be difficult in patients with few small lesions and without familial history of the disease (25). Yet, a series of clinical criteria and a few biomarkers have been defined (26). A GVM is usually raised, nodular, present at birth, and slowly expands during childhood (Figure 56-1). It is often multifocal and hyperkeratotic. Its color varies from pink to purplish-dark blue (25). Sometimes, it is flat and purple

**FIGURE 56-1** Venous anomalies: GVM on leg; cutaneous and mucosal venous malformations (VMCMs) on lips; sporadic VM on foot; HCCVM on arm; multiple spindle cell hemangioendotheliomas and enchondromas on hand of patient with Maffucci syndrome; intestinal and cutaneous VMs of patient with BRBN syndrome; CLVM on legs of patient with KTS (left side more affected).

in color, especially in the newborn. This plaque-like GVM usually darkens with time (27). GVMs are mainly located on the extremities, involve skin and subcutis, and are often painful on palpation. They cannot be completely emptied by compression. Contrary to a VM, a GVM is rarely encountered in the mucosa (25). Patients with GVM have normal mental and physical development, normal blood cell counts, coagulation, liver and renal function, electrolytes, plasma proteins, and urinalysis. They do not have intestinal hemorrhage, which distinguishes them from patients suffering from blue rubber bleb nevus (BRBN) syndrome (OMIM 112200) (28). D-dimer level is normal in GVM (29). In two patients, thoracic-plaque-type GVM was associated with pleural effusion (30).

The alterations in the mutated gene seem to cause specifically abnormal cutaneous vascular development. Currently, the best therapy is surgical resection of the entire GVM, which is curative, and is facilitated by the non-infiltration of GVM in underlying tissues (25). Alternatively, sclerotherapy can be used for a GVM that is soft on palpation.

GVMs are caused by loss-of-function mutations in the gene encoding glomulin (*GLMN*); the function of the protein is unknown (31). Glomulin has 594 amino acids. So far, 40 distinct mutations have been reported in 162 families (22,31–34). Sixteen of the mutations were detected in several families, accounting for almost 85% of the pedigrees with a *GLMN* mutation. The most frequent mutation is *c.157\_161del* (a.k.a. *157delAAGAA*), present in 72 kindreds (44.4%). Screening for these shared mutations first accelerates genetic diagnosis (22).

There is no correlation between the position of a mutation in the *GLMN* gene and characteristics of the disorder, such as the number of glomus cells in the lesion, the extent of the lesion, or the number of lesions. Yet, for the same mutation, the expressivity is variable

**FIGURE 56-2** Signaling pathways involving glomulin (GLMN) and TIE-2 in normal and pathological endothelial and vSMCs. Lack of GLMN signaling results in aberrant differentiation towards glomus cells. Pathways chronically activated by *TIE-2* mutations highlighted in orange; with the exception of STAT1, all are also activated by wild-type receptor, upon stimulation.

from patient to patient (22). Several observations suggest a paradigmatic mode of inheritance for GVM, instead of a simple autosomal dominant transmission. GVM has an age-dependant variation in penetrance, which reaches its maximum (92.7%) by 20 years of age (31). Unaffected mutation carriers have been identified in GVM families and affected individuals develop new lesions by time, albeit they stay small (25). This multifocality can be explained by the occurrence of double-hit mutations in glomulin (31,35).

In GVMs, the mural glomus cells are round or polygonal, instead of elongated like the normal vSMCs (12,36). Glomus cells stain positively for smooth muscle  $\alpha$ -actin and vimentin, whereas they are negative for desmin, von Willebrand factor, and S-100 neuronal marker (36). During murine development, glomulin RNA was first detected at E10.5 dpc in cardiac outflow tracts, and later, strong expression was seen in vSMCs (37). In contrast, glomus cells do not express the late markers of vSMC differentiation glomulin and smoothelin-b, whereas two earlier markers, smooth muscle myosin heavy chain and h-caldesmon, were detected (35). Thus, it seems that glomus cells have deviated in their differentiation process due to lack of glomulin expression.

Glomulin has no known motif or conserved domain. It may act synergistically to control both TGF $\beta$  and

hepatocyte growth factor (HGF) pathways (Figure 56-2), which are crucial for vSMC differentiation (38,39). In vitro, glomulin interacts with FKBP12 and might impede its binding and inhibition of TGF $\beta$  receptor signaling (40,41). FKBP12 also inhibits downstream signaling of mTOR (42,43). Complete loss of glomulin in GVMs could thus result in inhibition of TGF $\beta$  and mTOR signaling. Glomulin also interacts with the intracellular part of the HGF receptor c-Met. Upon HGF binding, glomulin is tyrosine-phosphorylated, released, and induces phosphorylation of p70S6-kinase (41), thereby controlling protein synthesis (42,43). As HGF triggers downstream signaling mediating vSMC migration (39), lack of glomulin in GVMs likely alters this signaling. Glomulin was also reported to interact with Cul7, with which it forms an SCF-like complex (44). These complexes are E3-ubiquitin-ligases, determining the specificity for the substrate to ubiquitinate. Thus, glomulin–Cul7-containing complex may regulate protein degradation in vSMCs, and affect their differentiation.

### 56.3.2 Inherited Venous Malformation

A second, less common inherited VM is the autosomal dominant multiple cutaneous and mucosal venous malformation (VMCM; OMIM 600195), which accounts

for another 1–2% of all VMs (11). It is characterized by multiple small, compressible blue lesions on the skin and mucosa, commonly located in the cervicofacial region and the limbs, and less often on the trunk (Figure 56-1). Histologically, distended venous channels are lined by a single endothelial cell layer surrounded by sparse, irregularly distributed vSMCs (45). VMCM is caused by mutations in *TEK*, located on chromosome 9p21 (45–47). *TEK* (also called TIE-2) is an endothelial cell tyrosine kinase receptor that binds the angiopoietins ANGPT 1, 2, and 4 (Angpt3 in mice) (48–50). The resulting modulation of downstream signaling molecules, including PI3K/Akt and mitogen-activated protein kinase (MAPK) (51,52), is critical to endothelial cell survival and function (Figure 56-2) (49,53,54). Eight intracellular mutations have been identified, which cause widely variable ligand-independent hyperphosphorylation of the receptor in vitro (45–47). The most commonly identified change, R849W (10/17 families reported), was shown to be accompanied by a somatic loss-of-function of the wild-type receptor in one lesion, locally abolishing some putative protective/competitive effect of the latter (55). As in the case of GVM, this likely explains why the germ line mutations do not cause generalized vascular abnormalities despite being ubiquitous, instead resulting in highly focal malformations only where their effects are compounded by an additional somatic hit.

### 56.3.3 Sporadic Venous Malformation

By far the most frequent (95%) of the VMs are those that occur sporadically, and therefore, unpredictably. Histologically similar to VMCMs, sporadic VMs (OMIM 600195) are usually much larger, single lesions that affect the skin and mucosa (Figure 56-1), but can also infiltrate underlying tissues in various organ systems (11). They can cause significant morbidity due to their size, localization, or expansion, making them the malformations most frequently treated at centers specializing in vascular anomalies (11). In about 42% of patients, localized intravascular coagulopathy, characterized by elevated levels of D-dimers, is observed, and correlates with the size and depth of lesions and the presence of phleboliths (29,56). While compression, sclerotherapy, and surgical removal are currently employed, these approaches can be problematic and ineffective, depending on the nature and location of the lesion, and regrowth is common (26). More targeted treatments, guided by insights into the pathogenic mechanisms involved, are therefore sought.

An appreciation of the widespread role of somatic events in inherited vascular malformations prompted researchers to focus on surgically resected lesions. This led to the discovery that somatic intracellular mutations in *TEK* cause at least 50% of sporadic VMs (55). As with VMCM, these are characterized by ligand-independent hyperphosphorylation of the receptor in vitro. Amongst the changes is the frequent L914F (69%

of mutation-positive samples), which has never been observed germ line among VMCM families, suggesting it is lethal when ubiquitous (55). The somatic changes also include a series of double mutations that occur in *cis* (on the same allele) (55,57). The constituent single mutations include three that cause premature truncation in the C-terminal tail domain, yet cause receptor phosphorylation (57), likely by abolishing its customary inhibitory fold. Double *cis*-mutations seem to predispose to multifocal sporadic VMs. Patients with this rare form have the same mutations in their multiple lesions, although they are undetectable in the blood (55) (Soblet et al., unpublished). This would suggest the multiple VMs were all seeded by a common cellular progenitor in which the somatic mutation had occurred.

The mechanism by which chronic TIE-2 activation causes VMs is unknown. R849W, being the first mutation identified, is the most studied, and has been shown to have a Shc- and pAkt-dependent pro-survival effect on ECs (Figure 56-2) (58–60). While this could account for why they survive despite the lack of support and cross-talk with smooth muscle cells, it does not explain the defective recruitment of the latter. R849W does not seem to influence proliferation or migration in vitro, but does lead to the formation of more unstable tubes as compared with cells bearing the wild-type receptor (58). It causes increased basal as well as lipopolysaccharide-induced phosphorylation and activation of STAT1, an inflammatory mediator (58,61). What this implies for VM-pathology is unknown. Inherited R849W and somatic L914F both affect the subcellular localization of the receptor in overexpressing human umbilical vein endothelial cells (HUVECs) (55). While R849W is evenly distributed on the cell surface, similarly to the wild-type receptor, L914F seems to be sequestered in the Golgi and ER, where it is strongly hyperphosphorylated. It is not exclusively perinuclear in distribution, however, as evidenced by the fact that a proportion translocates to the retracting edge of cells in response to ANGPT 1 (55). This movement is much more pronounced in the case of R849W, which is also more highly concentrated and phosphorylated in long retracting fibers than the wild-type receptor (55). The two common changes, therefore, seem to have distinct if overlapping functional effects. The lack of any clear correlation between patient phenotype and the strength of receptor phosphorylation (55,57) suggests that pathogenesis results, not merely from a quantitative increase, but also qualitative abnormalities in signaling downstream of TIE-2, potentially due to its localization in compartments with inappropriate interacting molecules.

### 56.3.4 Hyperkeratotic Cutaneous Capillary–Venous Malformation

Multiple cutaneous- and capillary-VMs sometimes occur in association with cerebral cavernous malformation

(CCM; OMIM 116860), described in detail in Chapter 57. Characterized by distended capillary-like channels without any intervening brain parenchyma, CCM can be asymptomatic, but often causes headaches, focal neurological defects, seizures, or hemorrhage (62). A systematic analysis of the cutaneous lesions associated with familial forms of the anomaly in a large cohort showed that hyperkeratotic cutaneous capillary–venous malformations (HCCVMs; OMIM 166860) are exclusively associated with mutations in *CCM1* (*KRIT1*) (63). Nodular VMs are associated with mutations in *CCM3* (*PDCD10*), and sometimes *CCM1*, albeit less frequently (63). Mutations in the third gene known to cause CCM, *CCM2* (malcavernin/*MGC4607*), are rarely, if ever, associated with VMs. HCCVMs are plaque-like, irregular, black or crimson lesions, with the ECs of the venous channels surrounded by two or more layers of smooth muscle cells (Figure 56-1). Nodular VMs appear more similar to multifocal sporadic VMs (64). Histologically, they are similar to the cerebral lesions of CCM, and consist of several thin-walled channels, packed together and surrounded by a fibrous layer containing smooth muscle cells (63).

### 56.3.5 Other VM-Associated Syndromes

VMs also arise in the context of sporadic syndromes such as BRBN (OMIM 112200) and Klippel–Trenaunay (OMIM 149000), the etiologies of which are unknown. BRBN is characterized by multiple small, rubbery cutaneous VMs, often on the plantar surfaces (Figure 56-1). Their association with gastrointestinal VMs, which can cause bleeding and anemia, forms the basis of the

diagnostic criteria (11,26). Klippel–Trenaunay syndrome (KTS), a detailed description of which is included in Chapter 50 (Hereditary Disorders of the Lymphatic System), also involves the venous component of the vascular system. It is characterized by capillary–lymphatic–venous malformations (CLVMs) on a hypertrophic extremity, most often a lower limb (Figure 56-1) (11,65). Abnormal capillary–venous channels in the form of spindle cell hemangioendotheliomas are seen in Maffucci syndrome (OMIM 166000), which also involves multiple enchondromas, benign tumors of the cartilage (Figure 56-1). There is a high rate of malignant transformation, most often to chondrosarcoma (11). *PTHR1*, the gene that can be mutated in enchondromatosis in Olliers disease (66), and *PTPN11*, which can be mutated in metachondromatosis (67), have not been found to be mutated in Maffucci syndrome. Genome-wide single nucleotide polymorphism mapping arrays, performed on the blood and tissue from patients, have revealed several somatic deletions and losses of heterozygosity in the tumors, although none was common to all or most samples (68).

## 56.4 CONCLUSION

The discovery that loss of glomulin function or aberrant TIE-2 activation causes more than 50% of all VMs makes known or novel inhibitors of the related pathways potentially useful therapeutic candidates. Further insights into the pathways dysregulated by TIE-2, *GLMN*, and other molecules that cause venous disorders could reveal additional suitable targets for these anomalies (see Table 56-1 for a summary). The availability of good animal models

**TABLE 56-1 Disorders Affecting the Venous System**

Malformation/ Syndrome	Inheritance <sup>a</sup>	OMIM	Locus	Mutated Gene	Features
GVM	AD	138000	1p21–22	<i>GLMN</i>	Raised hyperkeratotic bluish nodules on skin, often painful; enlarged venous channels with rounded vSMCs (i.e. glomus cells)
Multiple cutaneous and mucosal venous malformation (VMCM)	AD	600195	9p21	<i>TIE-2 (TEK)</i>	Soft bluish masses on skin and mucosa, often multiple; enlarged venous channels with patchy vSMCs
Sporadic VM	SP	600195	1p21–22	<i>TIE-2 (TEK)</i> somatic	Same as VMCM, usually a single large lesion; no family history
BRBN syndrome	SP	112200	?	?	Resembles VMCM, associated with gastrointestinal lesions that can bleed
KTS	SP	149000	?	?	CLVMs on hypertrophic extremity (usually lower limb)
Maffucci syndrome	SP	166000	?	?	Abnormal capillary–venous channels associated with multiple enchondromas and frequently chondrosarcomas
Cerebral cavernous malformation (CCM) with nodular VM	AD	116860	7q11–22	<i>KRIT1</i>	Nodular VM associated with brain, spinal cord, retinal, and cutaneous dilated channels with loose ECs, causing headaches, seizures, and hemorrhages
HCCVM	AD	116860	7q11–22	<i>KRIT1</i>	Same as CCM, with plaque-like hyperkeratotic cutaneous lesions

<sup>a</sup>AD, autosomal dominant; SP, sporadic; ?, unknown.

of (glomus) VMs, currently lacking, would allow for the testing of potential therapies for their safety and efficacy.

## Biographies

Dr Miikka Vikkula, MD, PhD, obtained his MD at the University of Helsinki in 1992 and his PhD in molecular genetics, with a thesis on collagens and cartilage disorders, in 1993 (Prof. Leena Peltonen). He was a research associate at the Department of Cell Biology at Harvard Medical School (Prof. Bjorn R Olsen) between 1993 and 1997, during which time he became interested in vascular anomalies. With his wife, Prof. Laurence Boon, MD, PhD, plastic surgeon, the couple discovered the gene for familial venous malformation in 1996. They settled in Brussels in 1997, where Dr Vikkula started to develop his own laboratory as a guest investigator at the de Duve Institute between 1997 and 2000. He obtained a “docentship PhD” in human molecular genetics at the Université catholique de Louvain (UCL), Brussels, in 2000, and was thereafter nominated assistant professor at the Faculty of Medicine in UCL. He has been a full member of the de Duve Institute, and a member of the directorat since 2004. He was nominated Professor of Human Genetics at the Université catholique de Louvain on 1 October 2008. Prof. Vikkula is well known internationally as a major contributor to the understanding of the molecular basis of lymphatic and vascular anomalies and lymphedema, with many high impact publications. He has been an invited speaker at numerous major scientific meetings. He has also received numerous honors and awards from a number of prestigious organizations for his academic achievements; most recently, the Lacroix Prize on cardiovascular disorders, 2010; the Pfizer Scientific Award, 2006; and the Eugène de Sommer Scientific Award, UCL, Belgium, 2006.

Dr Nisha Limaye obtained her PhD at the University of Texas Southwestern Medical Center in Dallas, Texas, in the laboratory of Dr Edward K Wakeland. Her work focused on the genetic basis of pathogenesis in a murine model of the complex autoimmune disease systemic lupus erythematosus. She moved to Brussels, Belgium, in 2005, and became interested in the genetic underpinnings of vascular anomalies in the course of her postdoctoral work in the laboratory of Prof. Miikka Vikkula, where she remains as an associate member of the de Duve Institute in Brussels, Belgium. In 2010, she was nominated a “Chercheur Qualifié”, becoming a permanent member of the National Research Funding Agency of Belgium.

**Pascal Brouillard**, PhD, graduated in biochemistry at the University of Liège, Belgium, in 1997. The same year, he started as a PhD student in the Laboratory of Human Molecular Genetics (Prof. Vikkula), de Duve Institute, Université catholique de Louvain (UCL), Brussels, Belgium, where he studied vascular anomalies. More precisely, he discovered the glomulin gene, mutations in which cause glomuvenous malformations. Moreover, he found that the lesions need a second-hit mutation for development. It was the first time such a mechanism was reported in vascular anomalies. He obtained his PhD in 2003. Since then, he has pursued his postdoctoral studies in the same laboratory, mainly focusing on the generation of various glomulin mouse models. Between 2003 and 2007, he was a research associate of the Fonds National de la Recherche Scientifique (FNRS, Belgium), and is now a research associate of UCL. Pascal was laureate of the FBBF Belgian Biotechnology Fund Research Award in 2005, and is a member of the Belgian Society of Human Genetics and of NAVBO.

**Professor Laurence Boon**, MD, PhD, obtained her MD at the Université catholique de Louvain, Brussels, Belgium, in 1989, and became a plastic surgeon in 1996. During her training in plastic surgery, she spent two years at the Children's Hospital, Boston, and the Harvard Medical School, under the supervision of Professor John B. Mulliken, to specialize in vascular anomalies. At the same time, she was a research associate at the Department of Cell Biology, and with her husband, discovered in 1996 the gene for familial venous malformation. Since 1996, she has been in charge of the Center for Vascular Anomalies at the University Hospital of St Luc, Brussels, Belgium. She obtained a PhD in plastic surgery in 2003, with a thesis on "New Clinical and Molecular Genetic Criteria for Hemangiomas and Venous Malformations."

Prof. Boon is well known internationally for the management of vascular anomalies and as a major contributor to the understanding of the molecular basis of vascular anomalies, with several high impact publications, reviews, and chapters on vascular anomalies. In 2003, she was invited to give the Sidney Hurwitz Memorial Lecture at the American Pediatric Dermatology Meeting in Seattle, USA. Since 2008, she has been the chair of the scientific committee of the ISSVA (International Society for the Study of Vascular Anomalies). She has been an invited speaker at numerous major scientific meetings. She continues to develop the multidisciplinary Center for Vascular Anomalies in Cliniques universitaires St Luc in Brussels. The Center will celebrate its 20th anniversary in 2011. Prof. Boon is involved in several research projects aimed at elucidating the pathophysiology of these anomalies as well as in clinical trials of new medications for vascular anomalies.

### 57.1 INTRODUCTION

Vascular anomalies are a heterogeneous group of disorders divided into tumors and malformations based on clinical, radiologic, and immunohistochemical studies. Vascular malformations are considered to be localized defects of vascular morphogenesis. They are present at birth, even if not always visible, and based on the type of the affected vessel, they are classified into capillary, venous, arterial, and lymphatic malformations. Sometimes, more than one vessel type is involved (combined vascular malformations), such as arteriovenous malformation, capillary–venous malformation, etc. Vascular malformations are in general sporadic, but familial forms exist, enabling genetic studies and the identification of genes involved in vascular morphogenesis, which can lead to proper genetic counseling and development of targeted therapies. This chapter reviews sporadic and familial capillary malformation with a special emphasis on cerebral cavernous malformation and capillary malformation–arteriovenous malformation. Hereditary hemorrhagic telangiectasia is discussed in Chapter 49.

### 57.2 CAPILLARY MALFORMATION

Capillary malformation (CM) (Figure 57-1A) or “port-wine stain,” with an incidence of 3/1000 is the most frequent vascular malformation (1). Histologically, CM is formed of dilated capillary-like channels,

the number of which increases with age. It is usually an isolated, sporadic, solitary flat lesion, present at birth, and grows proportionately with the child and persists throughout life. CM is a slow-flow, homogenous lesion of variable size, with geographic borders, located mainly on the skin and sometimes on the mucosa, appearing as a red macula that darkens and often thickens with age. It is located on the head, neck, trunk, or limbs, and the underlying tissues (skin, fat, muscle, and bone) can be hypertrophic.

CMs are asymptomatic, but can generate important psychosocial distress. Often they do not require any treatment. When necessary for unsightly reasons, laser, mainly pulsed-dye, is the first line treatment. Laser treatment reduces the coloration in 75% of patients without modifying skin texture. It requires many sessions and necessitates general anesthesia in children and in adults with large CMs. When laser is ineffective, surgery is an option and it can also be used to reduce tissue hyperplasia.

CMs have to be differentiated from common nevus flammeus, present in up to 50% of newborns and located on the back of the neck, forehead, eyelids, or upper lip. Hypertrophic CM located on a limb has to be differentiated from Klippel–Trenaunay syndrome (capillary–lymphatic–venous malformation; Online Mendelian Inheritance in Man (OMIM) 149000; see Chapter 50) and Parkes Weber syndrome (capillary malformation, arteriovenous micro fistulas, and hypertrophy; OMIM 608355; see Section 57.4).

**FIGURE 57-1** Disorders of the capillaries. (A) Sporadic capillary malformation (CM). (B–G) Phenotypic variation in capillary malformation–arteriovenous malformation (CM-AVM): (B) Nose AVM and small CM on the left cheek; (C) T1-weighted MRI enhanced sequence of the AVM shown in B; (D and E) CM of CM-AVM—small multifocal CM with halo (arrows); (F and G) Parkes Weber syndrome in the lower extremity: patchy CM and hypertrophy. (H and I) sporadic cerebral cavernous malformation (CCM) lesion (arrow) in the parietal lobe: axial T2-weighted MRI sequence (H) and axial T2-weighted gradient-echo sequence (I). (J) Multiple supratentorial CCMs (arrows)—axial T2-weighted gradient-echo sequence.

Sometimes, a capillary blush can be observed on top of an arteriovenous malformation and can be misinterpreted as a CM.

### 57.3 STURGE-WEBER SYNDROME

Particular attention has to be paid to CM located on the territory of the first branch of the trigeminal nerve (V1), which in 10% of cases is part of Sturge–Weber syndrome (OMIM 185300). This is a sporadic, severe neurocutaneous disorder, with an estimated incidence at 1/50,000 and unknown etiology. Males and females are equally affected. It manifests as a unilateral capillary malformation present at birth and located on the forehead and the upper eyelid (V1), ipsilateral leptomeningeal capillary-venous anomaly, and ocular involvement. The capillary malformation can be bilateral and/or more

extensive, covering the territory of the maxillary (V2) and mandibular (V3) branches of the trigeminal nerve, and sometimes the trunk and the limbs. In rare cases, the CM can be absent.

Seventy-five percent of children with intracranial vascular anomaly develop seizures, most often before age 2 years, with a risk of contralateral neurologic deficit and learning difficulties. Gyral calcifications can be observed. The major ocular complication is glaucoma, occurring in more than 50% of patients, requiring regular ophthalmologic follow-up throughout life, but especially in infants. Management of epilepsy and glaucoma is an emergency. It is still questioned if prophylactic anticonvulsant treatment is recommended or not. Pulsed-dye laser can be used to treat the facial CM, once the seizures are controlled. In patients with intractable seizures, surgery (lobectomy) may be required.

Even if most CMs are sporadic, some are familial, as those seen in CM-AVM (capillary malformation–arteriovenous malformation), CCM (cerebral cavernous malformation) or HHT (hereditary hemorrhagic telangiectasia). These three conditions have an autosomal dominant transmission. The first two conditions are discussed here, whereas HHT is discussed in Chapter 49.

## 57.4 CAPILLARY MALFORMATION–ARTERIOVENOUS MALFORMATION

Linkage studies in families with inherited capillary malformations allowed the identification of a susceptibility locus on 5q (2,3) and subsequently the recognition of *RASA1* on 5q14.1 (OMIM 139150) as the mutated gene (4). About 130 families with heterozygous *RASA1* mutations have been identified until now (4,5). This autosomal dominant condition is characterized by multifocal CMs and fast-flow vascular malformations: arteriovenous malformations (AVM), arteriovenous fistulas (AVF) and Parkes Weber syndrome (Figure 57-1B–G). The condition has been named capillary malformation–arteriovenous malformation (CM-AVM; OMIM 608354).

The penetrance is high, at more than 95%, and de novo occurrence is around 30%. The expressivity is variable even within the same family and the prevalence at least 1/100,000. All the affected people have CMs, but in contrast to classical CM, CMs of CM-AVM are often multifocal and small, less than 1 cm, round or oval, randomly distributed, and frequently surrounded by a pale halo. New lesions can appear during childhood.

About 30% of individuals with *RASA1* mutations have, in addition to multifocal CMs, fast-flow vascular malformations located in or outside of the central nervous system (CNS). In contrast with hereditary hemorrhagic telangiectasia, no lung or liver AVMs/AVFs have been observed. Lesions in the CNS include intracranial pial AVM/AVF, vein-of-Galen aneurysmal malformation, and spinal lesions (4–8). Around 10–12% of patients have symptomatic CNS fast-flow lesions; they present with cardiac failure or neurologic signs usually early in life, at birth or, before the age of 6 years. Neurologic symptoms include migraine, hemorrhage, epilepsy, and focal neurologic deficit. In about 20% of patients with *RASA1* mutation, the fast-flow vascular malformation is located outside the CNS. Half are AVM/AVF on the head and neck region or extremities, involving cutis and subcutis and sometimes muscles and bones, and half have Parkes–Weber syndrome (PKWS; OMIM 608,355), which is characterized by a capillary blush on an extremity, multiple arteriovenous microfistulas, and bony and soft tissue hypertrophy.

CM-AVM was described only in 2003. Thus, understanding of the natural and clinical history is insufficient for developing guidelines for clinical management. Meanwhile, patients should be examined once a year by

a clinician aware of the phenotype and its complications (6). CMs are harmless lesions. In contrast to sporadic CM, CMs of CM-AVM do not respond well to pulsed-dye laser, although most of them are small and well tolerated. Fast-flow lesions in the CNS in CM-AVM patients seem to manifest early in life. Nevertheless, regular brain magnetic resonance imaging (MRI) is recommended until natural history is better understood. These lesions, as well as extracranial fast-flow lesions, require a multidisciplinary approach, as in isolated AVM and AVF. Patients with Parkes Weber syndrome should be treated conservatively; epiphysiodesis for leg length discrepancy should be avoided when possible as it can aggravate the fast-flow vascular malformation (9).

Most of the *RASA1* mutations are nonsense, splicing, or out-of-frame deletion/duplication mutations, leading to premature termination and suggesting loss of function. This is further supported by the recent observation of large genomic *RASA1* rearrangements in the context of a new microdeletion syndrome in 5q14.3 (10). These patients present with severe mental retardation and absent speech, hypotonia, stereotypic movements, epilepsy, cerebral malformations, and mild facial dysmorphism due to *MEF2C* haploinsufficiency (10–12). When *RASA1* is included in the microdeletion, multifocal CMs are an important clue for the diagnosis.

The pathophysiology of CM-AVM is unknown, but the number of lesions and their localized nature could indicate that a somatic second hit is required for the lesions to develop, as previously reported in other multifocal vascular malformations (13–18). *RASA1* encodes p120RASGAP, a multi-domain cytoplasmic protein that acts as a negative regulator of the RAS-signaling pathway. P120RASGAP is a GTPase-activating protein (GAP) of RAS p21. It accelerates the intrinsic GTPase activity of RAS p21, switching it from active GTP-bound form to inactive GDP-bound. In addition, independent from its GAP activity, p120RASGAP plays a role in proliferation, differentiation, and pro- and anti-apoptosis (19). In mice, the complete loss of *Rasa1* is lethal at mid-gestation with abnormal angiogenesis; chimeric murine embryos constituted from wild-type and *Rasa1*-deficient cells exhibit severe edema and grossly abnormal vasculature (20).

There are several other disorders caused by mutations in genes encoding proteins that regulate the RAS/MAPK (mitogen-activated protein kinase) pathway. Germline mutations in the *NF1* gene, homolog to *RASA1*, cause neurofibromatosis type 1 (OMIM 162200), and other disorders, such as Noonan syndrome, LEOPARD syndrome, cardio–facio–cutaneous syndrome, Costello syndrome and Legius syndrome, are caused by germline mutations in genes that encode components of the RAS/MAPK pathway. With a certain overlap, they are characterized by craniofacial features, and cardiac, cutaneous, and neurologic abnormalities, and some of them exhibit cancer predisposition. These

entities are grouped under the term of RASopathies (21,22).

### 57.5 CEREBRAL CAVERNOUS MALFORMATION

Cerebral cavernous malformation (CCM; OMIM 116860) is a vascular anomaly located in the CNS, either intracranial (Figure 57-1H–J) or intraspinal. It can be associated with retinal or cutaneous lesions. CCM consists of clusters of dilated capillary-like vessels in a dense collagenous matrix, without normal vascular supporting cells and with abnormal blood–brain barrier. Based on cerebral magnetic resonance and autopsy studies, the prevalence is considered to be 1/200–1/1000 (23,24).

Sporadic and familial forms have been described; usually one lesion is observed in sporadic patients and multifocal lesions in familial patients by gradient-echo MRI. The familial form represents around 50% in Hispanic American patients of Mexican descent, due to a founder effect, and 10–40% in other populations. Linkage studies followed by sequencing of positional candidate genes or loss-of-heterozygosity mapping identified three CCM genes: *CCM1* (7q; *KRIT1*), *CCM2* (7p; *MGC4607*) and *CCM3* (3q; *PDCD10*) (reviewed by (25,26)). A heterozygous mutation (72% in *CCM1*, 18% in *CCM2*, and 10% in *CCM3*) is identified in about 95% of patients with multifocal CCMs and positive family history, but in only about half of the patients with multifocal CCMs and unaffected parents (27,28). No CCM germline mutation is expected in sporadic cases with one cerebral lesion on gradient-echo MRI.

About 60% of the mutation carriers are symptomatic; associated symptoms are mainly seizures and cerebral hemorrhages, but also headaches and focal neurologic deficit, irrespective of the gene involved. The radiologic penetrance is much higher but not complete, even with the very sensitive gradient-echo MRI sequences, and this observation is important for genetic counseling. Even if symptoms can be observed at any age, most often the onset is around 30 years in familial CCM. Importantly, new lesions appear with age and the size of the lesions tends to increase. Symptoms do not seem to correlate with the number of lesions, but rather with their location. The most severe outcome is associated with those in brainstem and basal ganglia (25). Cutaneous lesions, including capillary malformation, venous malformation, and more specific hyperkeratotic cutaneous capillary–venous malformation (HCCVM), are seen in about 9% of patients, mainly associated with *CCM1* mutations (29). Current clinical guidelines for symptomatic patients recommend medical treatment for seizures and surgical removal in case of hemorrhage, focal neurologic deficit, or lesions associated with intractable epilepsy. Gradient-echo MRI is the gold standard technique for diagnosis and it is recommended in patients with neurologic symptoms. Some

clinicians also recommend brain MRI for surveillance of asymptomatic patients, but this is controversial, as asymptomatic lesions are usually not treated.

More than 150 distinct mutations in the three CCM genes have been reported (30–35). Most of them are nonsense, frame-shift or splice site mutations, suggesting loss of function as the most plausible mechanism. To explain the localized nature of the malformation and the number of lesions (one in sporadic versus multifocal in familial CCM), a double-hit mechanism with biallelic loss was proposed. The efforts to confirm this hypothesis have recently been successful with the identification of a second hit in each of the three CCM genes (13,16) in one lesion from a few patients. Using laser capture microdissection, the mutations were shown to occur in a subset of endothelial cells, but not in non-endothelial cells (13) and this was consistent with immunohistochemistry studies (36).

In parallel with the genetic studies, many biochemical and in vivo studies have been conducted in an effort to unravel the disease mechanism. Yet, many pieces from the puzzle are still missing. The three CCM genes are conserved across species. *CCM1* encodes KRIT1 (Krev interaction trapped 1; OMIM 604214), a scaffold protein, which contains several domains involved in protein–protein interaction. *CCM2* (*MGC4607*; OMIM 607929) encodes malcavernin, a scaffold protein containing a phosphotyrosine-binding domain (PTB), similar to that of ICAP1 $\alpha$ , one of the KRIT1 partners. *CCM3* (*PDCD10*; OMIM 603285) encodes PDCD10, a protein with no known functional domain. Studies in zebra fish showed that loss of *krit1*, *ccm2*, or *ccm3* orthologs causes cardiovascular phenotypes with dilated and thin-walled heart and vessels (37–40). Mice lacking *Krit1* or *Ccm2* die in mid-gestation with vascular defects and heterozygous mice, unlike human beings, do not develop vascular lesions (reviewed by (41)). Loss of *Pdcd10* in murine embryos leads to growth arrest at E8.0 prior to the onset of circulation (42).

The CCM proteins are expressed in a variety of tissues, yet the disorder involves mainly CNS small vessels. Although it is not completely proven, it appears that CCMs are due to a defect in endothelial cells. Loss of *Ccm2* in murine endothelial cells, but not in neuroglial precursor cells, leads to vascular defects (43–45). Yet, loss of *Ccm3* in murine neuroglia also leads to vascular defects (44). It has been shown that the three CCM proteins interact (*CCM2* is the linker between *CCM1* and *CCM3*), but they also have specific partners (28,40,46–48). These proteins seem to play a role in cell–cell junctions, cell shape and polarity, and possibly cell–extracellular matrix adhesion (reviewed by (49)).

Besides the disorders described in this chapter, CMs are observed as part of many other rare entities/syndromes of unknown etiology, such as macrocephaly–capillary

malformation (OMIM 602501; previously described as M-CMTC (macrocephaly–cutis marmorata telangiectatica congenita)) and diffuse capillary malformation with overgrowth, or Wyburn–Mason syndrome, etc.

### Biographies

**Dr Nicole Revencu, MD, PhD**, has been a consultant in clinical genetics since 2008. She qualified from the Université catholique de Louvain, Brussels, Belgium, in 1996. She then undertook clinical training in pediatrics at Saint-Luc Hospital/Université catholique de Louvain, and in 2001 she moved into clinical genetic training. From 2004 to 2008 she undertook a research project on genetics of vascular malformations in Professor Miikka Vikkula's lab. Her main clinical interests are dysmorphology, cleft lip and palate, and vascular anomalies. She participates to the teaching of clinical genetics to medical undergraduates and is a supervisor for residents in pediatrics in the clinical genetics module.

**Dr Miikka Vikkula, MD, PhD**, obtained his MD at the University of Helsinki in 1992 and his PhD in molecular genetics, with a thesis on collagens and cartilage disorders, in 1993 (Prof. Leena Peltonen). He was a research associate at the Department of Cell Biology at Harvard Medical School (Prof. Bjorn R Olsen) between 1993 and 1997, during which time he became interested in vascular anomalies. With his wife, Prof. Laurence Boon, MD, PhD, plastic surgeon, the couple discovered the gene for familial venous malformation in 1996. They settled in Brussels in 1997, where Dr Vikkula started to develop his own laboratory as a guest investigator at the de Duve Institute between 1997 and 2000. He obtained a "doctentship PhD" in human molecular genetics at the Université catholique de Louvain (UCL), Brussels, in 2000, and was thereafter nominated assistant professor at the Faculty of Medicine in UCL. He has been a full member of the de Duve Institute, and a member of the directorat since 2004. He was nominated Professor of Human Genetics at the Université catholique de Louvain on 1 October 2008. Prof. Vikkula is well known internationally as a major contributor to the understanding of the molecular basis of lymphatic and vascular anomalies and lymphedema, with many high impact publications. He has been an invited speaker at numerous major scientific meetings. He has also received numerous honors and awards from a number of prestigious organizations for his academic achievements; most recently, the Lacroix Prize on cardiovascular disorders, 2010; the Pfizer Scientific Award, 2006; and the Eugène de Sommer Scientific Award, UCL, Belgium, 2006.

**Professor Laurence Boon, MD, PhD**, obtained her MD at the Université catholique de Louvain, Brussels, Belgium, in 1989, and became a plastic surgeon in 1996. During her training in plastic surgery, she spent two years at the Children's Hospital, Boston, and the Harvard Medical School, under the supervision of Professor John B. Mulliken, to specialize in vascular anomalies. At the same time, she was a research associate at the Department of Cell Biology, and with her husband, discovered in 1996 the gene for familial venous malformation. Since 1996, she has been in charge of the Center for Vascular Anomalies at the University Hospital of St Luc, Brussels, Belgium. She obtained a PhD in plastic surgery in 2003, with a thesis on "New Clinical and Molecular Genetic Criteria for Hemangiomas and Venous Malformations."

Prof. Boon is well known internationally for the management of vascular anomalies and as a major contributor to the understanding of the molecular basis of vascular anomalies, with several high impact publications, reviews, and chapters on vascular anomalies. In 2003, she was invited to give the Sidney Hurwitz Memorial Lecture at the American Pediatric Dermatology Meeting in Seattle, USA. Since 2008, she has been the chair of the scientific committee of the ISSVA (International Society for the Study of Vascular Anomalies). She has been an invited speaker at numerous major scientific meetings. She continues to develop the multidisciplinary Center for Vascular Anomalies in Cliniques universitaires St Luc in Brussels. The Center will celebrate its 20th anniversary in 2011. Prof. Boon is involved in several research projects aimed at elucidating the pathophysiology of these anomalies as well as in clinical trials of new medications for vascular anomalies.

## Cystic Fibrosis

Garry R Cutting

McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine,  
Baltimore, MD, USA

### ABBREVIATION LIST

AAV – Adeno-associated virus  
 ABC – ATP-binding cassette  
 ASL – Airway surface liquid  
 CBAVD – Congenital bilateral absence of the vas deferens  
 CF – Cystic fibrosis  
 CFRD – CF-related diabetes  
 CFTR – Cystic fibrosis transmembrane conductance  
   regulator  
 DZ – Dizygous  
 ENaC – Epithelial Na<sup>+</sup> channel  
 FEV1 – Forced expiratory volume in 1 second  
 GI – Gastrointestinal  
 IRT – Immunoreactive test  
 IRT – Immunoreactive trypsinogen test  
 MZ – Monozygous  
 NPD – Nasal potential difference  
 ORCC – Outwardly rectifying chloride channel  
 PD – Potential differences  
 PI – Pancreatic insufficient  
 PS – Pancreatic sufficient  
 PTC – Premature termination codon  
 SES – Socioeconomic status  
 SNP – Single nucleotide polymorphism  
 TMD – Transmembrane domain

One of the earliest clinical descriptions of cystic fibrosis (CF) appeared in 1936 (1). It was termed CF of the pancreas in recognition of the feature that distinguished this illness from other causes of chronic gastrointestinal (GI) malabsorption (1). Recurrence of CF in families indicated a genetic etiology. Extensive pedigree analyses published in 1946 suggested an autosomal recessive pattern of inheritance (2). This implied that CF is caused by defects at a single locus. Monogenic inheritance was supported by review of CF pedigrees in Italian church records. Using consanguineous matings to expose recessive traits, Romeo and coworkers concluded that their results were most consistent with CF being a single-gene disorder (3). Cloning of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene on chromosome 7 and the

subsequent demonstration that CF patients have disease-producing mutations in *CFTR* confirmed the monogenic hypothesis for the classic form of the disease (4–6). However, it appears that genetic heterogeneity may account for a minor fraction of non-classic CF cases (7,8).

### 58.1 INCIDENCE OF CYSTIC FIBROSIS

Retrospective population-wide studies estimate that 1 in 3000 Caucasian newborns is affected with CF. This figure varies, however, by geographic location and population. A significantly higher frequency of CF, presumably as a result of genetic drift and/or founder effect, has been reported in several ethnic groups. Notable examples are the Hutterites in Alberta, Canada (incidence of 1 in 313), Afrikaaners in Southwestern Africa (1 in 622), and French-Canadians in the Saguenay-Lac St. Jean region (1 in 895) (9–11). Epidemiologic studies of more diverse populations have produced incidence estimates ranging from 1 newborn with CF per 1857 in Ireland (12) to an estimated 1 in 8000 to 1 in 9000 for the Hispanic population in Mexico (13). Overall, the majority of European, US, and Australian studies report an incidence of CF between 1 in 2000 and 1 in 4000 in Caucasians (14,15).

Newborn screening studies provide a different approach to estimating the incidence of CF. These studies utilized the serum immunoreactive test (IRT) either alone or in combination with DNA analysis (16–18). The incidence of CF in US newborn screening programs ranges from 1 in 3073 Caucasians in Colorado, 1 in 3938 Caucasians in Wisconsin to 1 in 5287 newborns in Western Pennsylvania (17,19,20). Adjustment of the Colorado data for testing compliance increased the estimated incidence to 1 in 2521, consistent with the generally accepted figure from retrospective studies. The lower estimate from Pennsylvania is likely the result of racial mixture (19) but CF may be less common among Wisconsin Caucasians (20). Two-tiered screening (IRT and DNA analysis) in South Australia revealed an incidence of 1 in 2821 newborns which compares reasonably

with the established incidence for that region (1 in 2200 newborns) (18,21). Studies from the United Kingdom, France, and Italy estimated similar newborn incidence of 1 in 2575, 1 in 2913, and 1 in 2650, respectively (22–24).

A third estimate for the incidence of CF in a mixed Caucasian population can be derived from the US CF Foundation Patient Registry. Clinical and epidemiologic data from all patients under care at CF Foundation Care Centers in the United States are collected by this registry. Over a 3-year period from 1990 to 1992, an average of 824 newly diagnosed Caucasian patients were reported to the CFF Registry. Adjusting by a coefficient of 1.21 for patients not followed in CFF Care Centers suggests an incidence of 1 in 3200 based upon 3,201,678 live Caucasian births (25). A fourth approach to estimate incidence utilizes heterozygote frequencies determined from population-based mutation screening. This method is particularly useful for determining incidence in a discrete population where the CF mutation frequencies are firmly established. For example, screening of Israeli Ashkenazi Jews for 5 CF mutations indicates a carrier frequency of 1 in 29 and estimates a population incidence of 1 in 3364 (26). Similar types of studies estimate an incidence of 1 in 1984 in Scotland (27) and 1 in 2916 in US Caucasians (28). Finally, comprehensive analysis of published CF incidence and corresponding frequencies of the common CF mutation  $\Delta F508$  from the same region

show significant correlation. This indicates that estimates of incidence based on newborn registries are a reasonably accurate reflection of the true regional incidence of this disease (29). Taken together, these studies indicate that an incidence of 1 in 2000 to 1 in 4000 newborns is most appropriate for Caucasians of European extraction. Epidemiologic and screening approaches both show variation in CF incidence by population, indicating that population-specific data should be used whenever possible.

The incidence of CF varies dramatically among different races. Case reports of the disease in native Africans and native Asians have been published but CF is rare in both populations (14,30,31). Reliable incidence estimates are not available for either race with the exception of one study of Asian Pacific Islanders living in Hawaii (1 in 90,000) (32). The incidence in black South Africans (1 in 12,000) and in African-Americans (1 in 15,000) is higher than native Africans probably due to Caucasian admixture (25,33). The same appears to be the case for individuals of Asian ancestry living in Canada or the United Kingdom (34,35). Indeed, CF incidence worldwide appears to be primarily determined by the degree of Caucasian admixture (Figure 58-1). However, screening of South African blacks for “African” CF mutations suggests that the incidence of CF may be considerably higher in native Africans (36). Case reports have also described CF in patients of Native American, Lebanese, Indian,

FIGURE 58-1 Worldwide Incidence of CF.

and Arabian background (14). Therefore, the diagnosis of CF should not be discounted on the basis of racial background, especially in multiracial countries such as the United States.

## 58.2 CLINICAL FEATURES

CF is a highly variable disorder. Classic CF usually manifests as recurrent pulmonary and/or GI disease in early childhood. Failure to thrive due to malabsorption and increased energy consumption is a common feature. These clinical features accompanied by an elevated concentration of chloride in sweat ( $>60$  mM) confirm the diagnosis of classic CF (see Section 6.4). About 60% of all CF patients are diagnosed before 12 months of age and 90% by 10 years old (37). Although an increasing number of patients are being diagnosed with CF as adults and almost half of the patients in the 2009 CF Foundation Patient Registry were 18 years or older, the median age of diagnosis has not changed substantially from prior decades (5 months of age in 2009) (38). Predicted survival age of patients in the United States in 2009 was 35.9 years (38). Pulmonary disease is the primary cause of mortality, accounting for nearly 90% of deaths (39,40). Liver disease and suicide account for another 2–3% of deaths (40). Not all features have to be present to make a diagnosis of CF. Patients with less obvious signs and symptoms of CF are frequently diagnosed in adulthood with non-classic forms of CF (Table 58-1) (41). Features of the CF phenotype in males are also observed in a separate autosomal recessive disorder called, congenital bilateral absence of the vas deferens (CBAVD) (Table 58-1) (42,43). Cloning of *CFTR*, the gene responsible for CF and identification of disease-associated mutations in patients with non-classic CF and CBAVD, confirmed that these variant phenotypes have the same molecular etiology as classic CF (44,45). However, there is evidence of genetic heterogeneity in CBAVD, and in non-classic CF (8,46).

### 58.2.1 Classic Cystic Fibrosis

Chronic cough, pulmonary infiltrates, reactive airway disease, and watery rhinorrhea are frequent symptoms.

TABLE 58-1 Phenotypes Associated with Mutations in the <i>CFTR</i> Gene			
	Classic CF	Non-classic	CBAVD
Chronic pulmonary disease	+	+	±
Pancreatic exocrine disease	+	±	–
Elevated sweat chloride ( $>60$ mM)	+	±	±
Male infertility	+	±	+

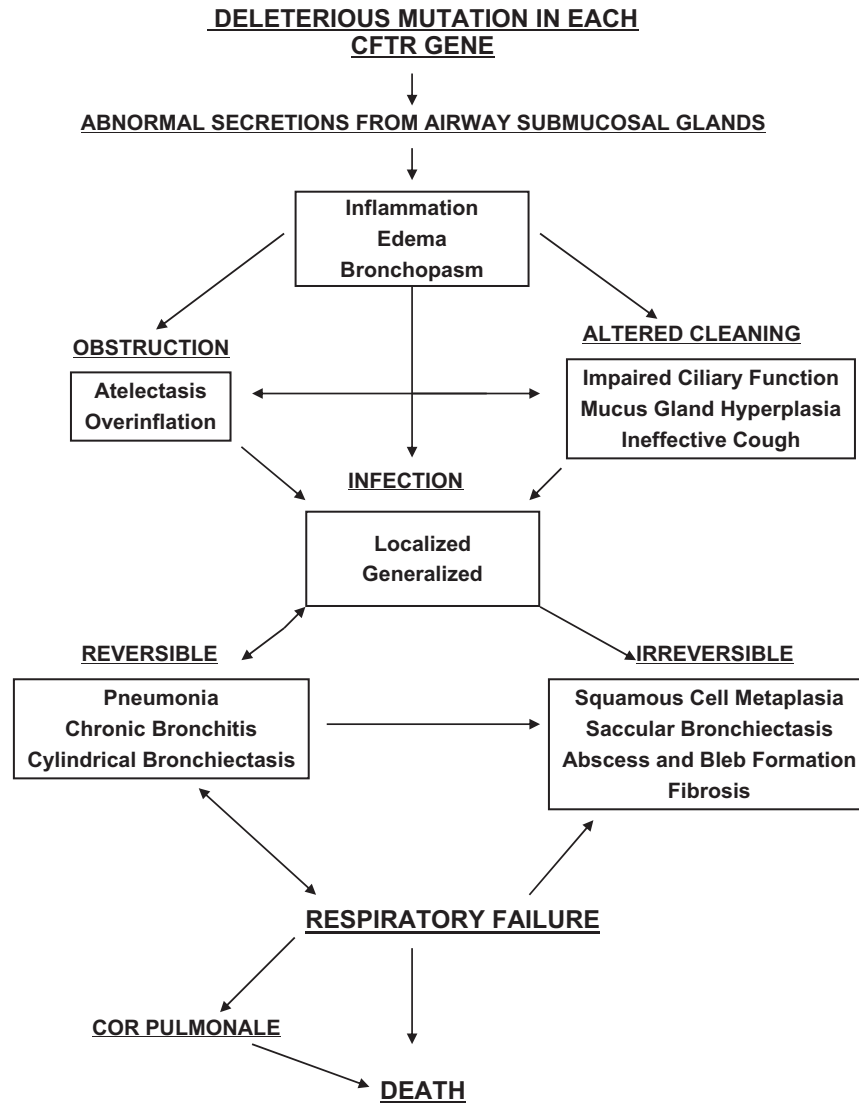

Neonatal intestinal obstruction due to meconium ileus (MI) and nasal polyposis in early childhood are particularly suggestive of this disorder (47–49). Pancreatic exocrine deficiency is present in 85–95% of patients and usually manifests as failure to thrive (50,51). Patients present with signs and symptoms of chronic protein and fat malabsorption including abdominal distension, and foul-smelling fatty stools (steatorrhea). Less common signs and symptoms at the time of diagnosis include electrolyte imbalance, rectal prolapse, and sinus disease (Table 58-2). Newborn screening accounted for 49.8% of the CF patients diagnosed in the United States in 2009 (38). It is likely that diagnosis of CF in the newborn period will become the most common form of presentation due to widespread use of screening in North America, Europe, and Australasia.

**58.2.1.1 Respiratory Disease.** Lung disease in CF manifests as recurrent episodes of infection and inflammation that leads to tissue destruction, fibrosis, and respiratory failure (Figure 58-2). Abnormally viscous mucus secretions initiate this downward spiral in lung function. At birth, the lungs of CF patients appear normal (52,53). Submucous glands in the large airways of CF newborns are similar in number and distribution to their non-CF counterparts (52,53). However, autopsy examination of infants dying from MI or other causes reveal dilation of acinar and duct lumens of submucosal glands due to obstruction with abnormal mucus secretions (53,54). Secretions from individual submucosal glands in nasal biopsies confirm that CF patients have high viscosity compared to normal subjects, leading to lower gland secretion rates in CF vs. normal subjects (55). Mucus impaction in the small airways (bronchioles) is also a consistent early finding (54,56). However, bronchioles have neither submucous glands nor evidence of prior infection (57). Identification of young infants

TABLE 58-2 Signs and Symptoms Suggesting a CF Diagnosis<sup>a</sup>

<sup>a</sup>Patients may present with one or more sign or symptom. Data from Ref. (40).

**FIGURE 58-2** Pathogenesis of Cystic Fibrosis in the Lungs.

with CF by newborn screening has enabled detailed in vivo study of the early manifestations of the disease. Significant increases in segmented neutrophils, elastase, and interleukin 8 levels in bronchoalveolar lavage fluid have been observed early in life and in the absence of infection (58). Inhibition of CFTR in normal airways increases submucous gland secretions (59). Both autopsy and in vivo studies indicate that submucous gland dysfunction may be the earliest manifestation of CF in the lungs (56,58). Gland dysfunction may lead to inflammatory changes in the lung and abnormal secretions that compromise lung defenses leading to airway infections that are a hallmark of CF (60) (Figure 58-2).

The next phase is local and generalized chronic bacterial infection confined to the lungs. CF lung disease is distinctive due to the unusual organisms involved. The initial infection is most frequently with *Staphylococcus aureus*, with *Hemophilus influenza* and *Pseudomonas aeruginosa* being less common (56,61). Over time, the airways become chronically infected, with *P. aeruginosa*

becoming the predominant organism (62). Colonization with this bacterium, especially mucoid strains, is highly unusual for normal lungs but almost pathognomonic for CF (63). Altered adherence properties of respiratory epithelium in CF patients may explain the predilection for specific organisms (64,65). Once established, eradication of these resident microbes is virtually impossible. Chronic *P. aeruginosa* lung infection with altered local defenses sets the stage for recurrent cycles of infection, inflammation, and tissue destruction (56,62,66,67). Over a period of years, this process moves from region to region decreasing the amount of functional lung tissue (56). Submucosal glands become hypertrophied, increase in numbers, and appear in the small airways (68). Dilation of the small and large airways (bronchiolectasis and bronchiectasis) is a characteristic finding on chest X-ray (69). The latter can lead to the development of cysts, usually affecting the upper lobes. Episodes of bacterial respiratory infection occur throughout the lifetime of the patient; often this process is peribronchial but interstitial

pneumonia also occurs in later stages. Damaged tissue is replaced by fibrosis adding restrictive lung disease to the underlying obstructive process. Ventilation/perfusion mismatches occur resulting in hypoxemia and cor pulmonale (70). At this final stage, death may occur due to severe hypoxemia, acute bronchial artery hemorrhage, tension pneumothorax, or cardiac complications (71).

Clinically, lung disease in CF presents as an intermittent but persistent cough. In many children, this may be accompanied by persistent wheezing viral infection and infiltrates (56,72). Over time, the cough becomes daily and productive. This situation usually remains stable for a number of years, occasionally interrupted by acute worsening of symptoms called pulmonary exacerbations. The episodes are treated with intensive antibiotic therapy and mucus clearance techniques to recover lung function. Tissue destruction accompanies these exacerbations, which become more frequent over time, causing an increased rate of progression of disease. Pulmonary function measures are used to document progression of diseases, among which, the forced expiratory volume in 1 second (FEV1) has proved most useful. FEV1 has been shown to be highly predictive of survival (73,74). It has been estimated that lung function declines exponentially by about 3% per year for the average patient, slightly more rapid for females than males (74,75).

The age of onset and the rate and pattern of lung disease progression are highly variable (56). The role of *Pseudomonas* infection in disease onset and progression is a matter of debate (61,67,76–78). However, conversion to mucoid strains of this bacterium or infection with relatively drug-resistant organisms (*Burkholderia cepacia*) has been associated with rapid disease progression (63,78–81). Other studies indicate that *B. cepacia* colonization is associated with a variable clinical course (82,83). Patients with residual pancreatic function may have less severe lung disease (74,84,85). Furthermore, certain CF mutations appear to be associated with milder lung disease than that observed in patients homozygous for the common CF mutation  $\Delta F508$  (74,86–88). However, in general, genotype is not predictive of pulmonary phenotype (85,89). Therefore, predicting the course of lung disease for a newly diagnosed patient is not possible due to the lack of accurate prognostic factors.

Epithelia similar to that found in the lung are also present in the nasal sinuses. Consequently, the mucus produced by the sinus epithelium is altered leading to obstruction of the sinus ostia (90). Thus, almost all patients with CF have radiographic evidence of sinus disease (91). A smaller fraction of patients have clinically significant sinus disease. The reported incidence of a complication of sinus disease, nasal polyposis, varies from 6 to 48% of CF patients (92). In general, about one in four patients has this complication (92). Polyps from CF patients have different histologic features than those found in patients with allergic symptoms (93). Chronic sinusitis associated with *Pseudomonas* infection

is a characteristic finding although the infection rarely spreads beyond the paranasal spaces (94). Fungus infection may also be present in the sinuses of some CF patients (95).

**58.2.1.2 Pancreatic Disease.** Dysfunction of the exocrine pancreas occurs to some degree in almost all patients (51). Malabsorption caused by pancreatic insufficiency was the prominent life-limiting feature of CF. Fortunately, replacement of digestive enzymes and vitamin supplementation has greatly reduced the complications associated with this manifestation. The pathologic process in the pancreas is similar to that observed in the lung (96). Abnormal mucus secretions cause obstruction and dilation of the pancreatic ducts. Pancreatic enzymes continue to be produced by the acini causing tissue destruction, cyst formation, and fibrosis. This process begins in utero and progressive destruction of the entire organ is ongoing (96). The degree of destruction usually correlates with the age of the patient (51).

Deficiency of pancreatic enzymes leads to malabsorption of protein, fat, and fat-soluble vitamins. Carbohydrate absorption is not significantly affected (97). Untreated, this situation can lead to a multitude of problems: steatorrhea and absence of adipose tissue, hypoproteinemia and edema, central nervous system, and visual disturbances due to deficiency of vitamins A and E, and bone demineralization and coagulopathy due to deficiency of vitamins D and K (51). These symptoms are rarely encountered in CF patients since most are treated with pancreatic enzyme supplementation. In 2009, 89.1% of patients in the US CF Foundation Patient Registry were taking enzyme supplements (38).

The severity of pancreatic disease is variable. About 5–15% of patients retain some degree of pancreatic function (51,96). These patients are termed pancreatic sufficient (PS), a condition associated with CFTR genotype (6,98,99). Serum levels of the pancreatic precursor enzyme, immunoreactive cationic trypsinogen, can distinguish between pancreatic insufficient (PI) and pancreatic sufficient (PS) patients over 7 years of age (100,101). Patients with residual pancreatic function may manifest recurrent episodes of pancreatitis (102).

Loss of function of the endocrine pancreas also occurs in CF. As the median age of CF patients has increased, CF-related diabetes (CFRD) has become as significant contributor to morbidity and mortality. About a quarter to half of CF patients have an abnormal glucose tolerance test by the third decade and over 25% of CF patients 35–44 years of age had a diagnosis of diabetes (38,51,103,104). Diabetes in CF patients displays a number of pathologic similarities with type 2 diabetes seen in the general population; incidence increases steadily with age (105), pancreatic islets have evidence of amyloid polypeptide accumulation (106), and insulin secretion decreases over time (107). Family-based studies demonstrated that a history of type 2 diabetes in one first-degree or at least two second-degree relatives was associated

with a substantial increase in risk of diabetes in a CF patient ( $OR = 3.1$ ) (108). Thus, pathways involved in the development of diabetes in CF appear to overlap with type 2 diabetes in the general population. Diabetes in CF patients has been associated with reduced pulmonary function, especially in females, poorer nutritional status, and reduced survival (109–112).

**58.2.1.3 Gastrointestinal Disease.** Disease in the GI tract of CF patients is usually less prominent than lung and pancreatic manifestations. However, several conditions are characteristic of CF. In neonates, obstruction of the distal small bowel by abnormally viscous meconium is virtually diagnostic of CF (47,48). This condition, termed meconium ileus, is believed to be the consequence of inadequate enzymatic digestion and/or hydration of the intraluminal contents of the small intestine (48). Clinically, the patient manifests symptoms of small bowel obstruction that can proceed to perforation and peritonitis (113). Presence of the abnormal meconium can interfere with fetal intestinal development producing atresia or volvulus (113).

MI with obstruction occurs in approximately estimate that 13–20% of CF patients present with this feature (47,48,89). Obstruction can occur in the large intestine of neonates (“meconium plug syndrome”) causing delay in the passage of the first stool and evidence of colonic obstruction (114). In uncomplicated cases of MI, radiologic studies using contrast enemas are not only diagnostic, but may also be therapeutic (115). Surgery is usually required for more difficult cases but survival rates are excellent and long-term prognosis is similar to CF patients without MI (113).

In children and adults, recurrent episodes of bowel obstruction due to distal intestinal obstruction syndrome (DIOS) are also characteristics of CF (71). The prevalence of DIOS is highly variable in CF patients ranging from 2.4% to 41.3% in different reports (116–118). Patients with MI have a significantly increased risk of DIOS supporting a common etiology. However, analysis of affected twins and siblings reveals that surgical treatment for MI appears to be the risk factor for developing DIOS in later life (119). Other forms of surgery, such as lung transplantation, also appear to be associated with higher rates of DIOS (120,121). Rectal prolapse in childhood is a very unusual situation but is not uncommon in children with CF (about 20%) (122). Other intestinal complications include intussusception and mucoid impaction of the appendix (123).

**58.2.1.4 Hepatobiliary Disease.** Liver disease occurs in a significant fraction of CF patients. Twenty-five percent of patients have focal biliary cirrhosis present at autopsy (124). However, clinical evidence of hepatic cirrhosis and portal hypertension occurs in only 2–3% of children and only 5% of adults (124). Radiographic studies reveal gall bladder abnormalities in about half of CF patients (125) but only 12% develop gallstones (cholelithiasis) (126). Jaundice and hepatocellular failure

are generally absent until end-stage disease develops. Abnormal mucus secretions in the bile ductules cause obstruction, dilation, inflammation, and focal biliary cirrhosis that progress to multilobular cirrhosis over time (127). Cholestasis in the neonatal period may present as prolonged jaundice (124). On exam, this cirrhotic process manifests as hepatosplenomegaly. Hemorrhage from esophageal varices can be life-threatening. Risk factors for the development of CF-related liver disease include male sex, a history of MI, and poor nutritional status (128–130). Whether CFTR genotype contributes to the development of liver disease is not clear (129–133).

**58.2.1.5 Sweat Glands.** Demonstration of elevated concentrations of chloride and sodium in eccrine sweat has been the diagnostic standard for CF since 1953 (134). The vast majority of patients with clinical features consistent with CF have chloride concentrations greater than 60 mM. Ninety-six percent of patients in the US Registry have sweat chlorides between 60 and 165 mM (104). About 3% are above 166 mM while 1.4% are less than 60 mM (discussed below as Atypical CF). Since values above 160 mM are not physiologically possible, it is likely that they represent testing error (135). At first glance, the high chloride concentration in sweat seems inconsistent with the underlying functional defect in CF; deficient chloride secretion. However, the sweat gland is composed of two regions: a secretory coil and a resorptive duct and both components are abnormal in CF patients. The coil secretes an ultrafiltrate in response to cholinergic and  $\beta$ -adrenergic agonists that is nearly isotonic with plasma. The  $\beta$ -adrenergic response of the secretory coil is consistently absent in CF patients (136). In healthy individuals, chloride and sodium are absorbed as the ultrafiltrate passes through the water-impermeable duct producing hypotonic sweat. In CF, chloride and sodium absorption of the duct is defective, leading to elevation of both electrolytes in sweat collected at the skin surface (137).

The major clinical manifestation of abnormal sweat gland function is salt depletion. This condition can present in young children as hypochloremic, hyponatremic alkalosis, and dehydration (103). Heat waves may precipitate acute volume depletion, whereas chronic salt-loss can be a common presenting sign in arid climates (138,139).

**58.2.1.6 Reproductive Tract Abnormalities.** A consistent abnormality caused by mutations in each CFTR gene is absence of atrophy or fibrosis of the vas deferens in men. This condition manifests as male infertility due to azoospermia in 96–97% of male patients with CF (140). Absence of secretions from the seminal vesicles causes chemical abnormalities in semen and a reduction in ejaculate volume (141). The pathogenesis of the vas deferens abnormality is unknown but is believed to be a consequence of mucus obstruction of the developing genitourinary tract. A separate genetic condition, CBAVD, is also associated with CFTR dysfunction (see below).

About 2–3% of males with CF are fertile and compound heterozygotes for two CF mutations have had offspring (45). Fertility in women with CF is reduced but not to the same degree as their male counterparts. Thick cervical secretions and menstrual irregularity due to chronic disease contribute to difficulties conceiving (103). Pregnancy was reported in 130 (4%) of 3,249 US female patients of reproductive age in 1993 (104). Just over half of these pregnancies resulted in a live birth. In 2009, 226 pregnancies were reported in 12,762 US females with CF.

### 58.2.2 Non-Classic Cystic Fibrosis and CFTR-Related Disorders

In the decade following the introduction of sweat test as the diagnostic standard for CF, it became apparent that adults could present with mild or incomplete phenotypes (142). Increased vigilance for “milder” forms of CF uncovered patients without clinical, chemical, or histological evidence of pancreatic disease (50,143–145). Diagnosis in these situations relied upon pulmonary illness consistent with CF and elevated sweat chloride concentrations. In males, azoospermia was an additional useful criterion for diagnosis (146). However, patients with suggestive features but sweat electrolyte concentrations below the range typical for CF (i.e., <60 mM) presented a diagnostic challenge, particularly if pancreatic function is preserved (147,148). Over the years, these patients have been variably referred to as non-classic, PS, intermediate, borderline, or atypical forms of CF (149,150). In this chapter, the term non-classic will be used to denote patients who have CF (based on clinical grounds) but manifest disease in only one or two of the classic triad of organ systems: lung, pancreas, and skin (i.e., sweat gland).

These observations indicated the existence of non-classic forms of CF where pulmonary history and exam suggested the diagnosis but sweat chloride concentrations were normal, or slightly above the normal range, but not diagnostic of CF (142,147). In 1978, Stern and colleagues presented seven patients fitting this profile (144). Sweat chloride concentrations were described as “intermediate” (40–60 mM). Since a significant fraction of normal adults have values in this range, additional criteria were used to suggest that these patients represented a variant of CF (144,151). Case reports of patients felt to have CF but with normal sweat chloride values (<40 mM) have also been published (148). The discovery of the CF gene has facilitated a molecular approach to the problem. Mutations in each CFTR gene have been identified in patients with non-classic disease confirming their inclusion in the CF spectrum (44,45,152). However, dysfunction of CFTR does not underlie all cases of non-classic CF (7,8).

More recently, non-classic CF has been differentiated from CFTR-related disorders such as male infertility due to CBAVD and pancreatitis where CFTR mutations are

present. The operating definition has been “a clinical entity associated with CFTR dysfunction that does not fulfill diagnostic criteria for CF” (150). An underlying reason to distinguish these two main categories is that classic and non-classic forms of CF are highly likely to result in reduced longevity while CFTR-related disorders are not. Thus, counseling and treatment decisions will differ considerably for the two categories.

## 58.3 GENETICS

CF is the most common lethal autosomal recessive disorder in Caucasians affecting about 1 in 3000–4000 newborns. This high incidence implies that approximately 1 in 30 individuals of European descent is a carrier of the disease. Explanations for the high frequency of CF alleles in Caucasians have included the coexistence of multiple CF loci (14), high mutation rate (153), genetic drift (32), founder effect (154), sex ratio and segregation distortion in favor of mutant alleles (155–160), and heterozygote advantage (161). Linkage analyses eliminated the hypothesis of multiple CF loci for classic CF (162). The identification of the CFTR gene and discovery of the major CF mutation ( $\Delta F508$ ) that is common in Caucasians, but rare in populations with a comparatively low incidence of CF (e.g., native Africans and Asians), provided a molecular basis for the high frequency of CF in Caucasians (4,6,29,163). Demonstration of a single origin of all  $\Delta F508$  mutations excluded high mutation rate (164). The high frequency of  $\Delta F508$  in large and heterogeneous European-derived populations argued strongly against genetic drift and founder effect, with the exception of ethnic isolates (154). Studies of sex ratio, segregation distortion, and a “hitchhiker” effect have been either inconclusive (155–159) or lack confirmatory evidence (160,165,166).

Heterozygote advantage of CF carriers remains as an attractive hypothesis. However, it is difficult to prove since it has been estimated that an advantage of as little as 1.6% per generation could account for the high incidence of CF (14,161). Various forms of heterozygote advantage have been proposed, including higher fertility of CF carriers (14,167,168), protection against bronchial asthma (169), and increased resistance to common infectious diseases (170–176). Fertility differences were found unlikely to have played an important role (177). Mouse models of CF have suggested heterozygote resistance to chloride-secreting bacterial diarrheas (176). However, this issue has been controversial since CF mutation distribution does not correlate with the geographic distribution of cholera (178). Furthermore, a second murine study and a human study did not find reduced intestinal chloride secretion in CF heterozygotes (179,180). These observations suggest that other factors may contribute to the high frequency of CF in Caucasians (181).

At least three cases of CF have been reported due to inheritance of both copies of chromosome 7 from one

parent (uniparental isodisomy) (182–184). The parent in each case was a heterozygous carrier of a CF mutation, thereby giving rise to a homozygous affected child. Although an interesting genetic phenomenon, this form of inheritance is extremely rare and should not be used to alter the risk estimates for healthy carriers of CF alleles (185).

### 58.3.1 Identification of the Gene Responsible for Cystic Fibrosis

**58.3.1.1 Mapping the Gene.** The first breakthrough in the mapping of the CF gene was a report of linkage between paraoxanase, a polymorphic enzyme in many populations and the CF locus (186). Soon thereafter, a DNA marker (DOCRI-917) was linked to the CF locus at a distance of approximately 15 cM (187). Mapping of this marker to the middle of the long arm of chromosome 7 located the gene responsible for CF, and facilitated the identification of additional markers (MET and D7S8) closer to the CF locus (188,189). Two collaborative studies demonstrated that these markers flanked the CF gene (190,191). The availability of DNA markers closely linked to the CF locus enabled accurate prenatal diagnosis and carrier detection to be performed in families with an affected individual (192).

**58.3.1.2 Approaches to Identify the Gene on Chromosome 7 Responsible for CF.** Scambler and colleagues took advantage of the close physical relationship between the MET oncogene and the CF locus (193). Using chromosome-mediated gene transfer, a short region of unmethylated CG-rich DNA was identified in a region encompassing the CF locus (194). A candidate for the gene responsible for CF was discovered close to the CG-rich region (194). The predicted amino acid sequence of the candidate gene resembled secreted “growth factors,” making this gene (termed IRP for *int*-related protein) an unlikely candidate for causing CF (195). Furthermore, the discovery of five families, each with a recombination event between IRP and the CF locus, eliminated IRP as the gene responsible for CF (195). However, two new DNA markers, XV2c in the IRP gene and KM19 from the 5′ region of IRP, had very few recombinations with CF in family studies (194). This indicated that XV2c and KM19 were considerably closer to the CF locus than either of the previously identified markers, MET and D7S8 (196,197). Furthermore, one particular pattern (haplotype) of the XV2c/KM19 markers was found on 85% of the CF-bearing chromosomes but was present on only 15% of normal chromosomes in North American and European Caucasian families (30,196,197). The high degree of linkage disequilibrium between XV2c/KM19-derived haplotypes and the CF locus confirmed the closeness of these markers to the gene, and suggested that a single mutation of this gene predominates in the Caucasian population.

**58.3.1.3 Cloning and Characterization of the *CFTR* Gene.** The gene causing CF, the *CF Transmembrane Conductance Regulator* or *CFTR*, was identified by a combination of chromosome jumping, physical mapping, isolation of exon sequences, and genetic analysis (4–6). *CFTR* is composed of 27 exons spanning 189 kb of DNA (198,199). The gene is transcribed into a mature mRNA of approximately 6500 basepairs (5). Alternative splicing of several exons has been described (200) and some of the resulting transcripts encode a functional isoform of CFTR (201–203). Several lines of evidence confirmed that *CFTR* is the gene responsible for CF (6). First, a common mutation, the deletion of three nucleotides ( $\Delta F508$ ), was found only on chromosomes from CF patients. Second, there were no recombinations between  $\Delta F508$  and the CF phenotype. Third, the  $\Delta F508$  mutation was almost exclusively associated with haplotype in strong disequilibrium with the CF locus. Finally, normal chromosomes with the haplotype common to CF chromosomes did not carry  $\Delta F508$ , indicating that this deletion was not a polymorphism linked to the “CF” haplotype (6).

*CFTR* mRNA is expressed in epithelial tissues classically affected in CF, such as the lung, pancreas, sweat gland, and liver (5). It has also been found in tissues of unclear or unknown involvement in CF, such as the large intestine and testis (204,205). RNA studies indicate a low level of *CFTR* transcripts (~1 per cell) in adult respiratory epithelium but much higher levels in pancreas and intestine (204,206). *CFTR* RNA can be detected in many regions of the developing lung but appears confined to airway epithelium of large and small airways by the perinatal period (207–209). Extensive *in situ* studies of *CFTR* expression in the rat reveals developmentally regulated expression in the male reproductive structures (204). Studies of *CFTR* protein expression have been generally consistent with RNA data. *CFTR* is barely detectable in surface epithelia of the lungs, although it is abundant in the pancreas, sweat gland, kidney, and intestines (205,210–214). *CFTR* expression in the lung is prominent in the submucosal glands, particularly cells in serous tubules and in occasional cells of the ducts (212,215). More detailed histochemical studies reveal that *CFTR* expression is confined to apical membranes of ciliated cells in the surface epithelium and gland ducts (216).

Although *CFTR* expression displays exquisite temporal and spatial regulation, sequences that control *CFTR* transcription are incompletely understood. The consensus of a number of studies indicates that the major transcription initiation site is approximately 70 nucleotides 5′ of the start site for translation (217–220). Elements for basal levels of expression reside within 360 nucleotides of the translation initiation codon (219). This region contains consensus sequences for an inverted CCAAT box and a cAMP response element (221–224). DNase I hypersensitive sites have been found within and flanking

the CFTR gene. These elements may facilitate tissue regulation of CFTR expression (225). Employment of newer techniques that map regulatory elements (e.g., enhancers) has identified DNA elements distant from the *CFTR* promoter (226,227) and within the *CFTR* gene (228,229). Other approaches to this problem include the identification of genomic regions that confer strain-specific differences in the expression of *Cftr* in mice and cross-species analysis to identify conserved non-coding regions that might harbor binding sites for regulators (230,231). The basal CFTR promoter does not seem to be regulated by methylation (203,232) although microRNAs that target the 3' region may play influence *CFTR* expression (233).

### 58.3.2 Properties of CFTR

**58.3.2.1 CFTR Is an Integral Membrane Protein.** The CFTR gene is predicted to encode a protein of 1480 amino acids that has two repeated structures each containing a transmembrane domain (TMD) composed of six hydrophobic segments and a putative nucleotide binding domain (NBD). These structures are separated by a 241 amino acid region with many charged residues and multiple potential sites for phosphorylation by protein kinases A and C (5) (Figure 58-3). The latter region was postulated to be involved in controlling protein function and was named the Regulatory or R domain. The overall structure of CFTR is most similar to members of the multi-drug resistance family and STE6, a yeast protein (5). These proteins belong to the superfamily of ATP-binding cassette (ABC) proteins which import or export small molecules (drugs, proteins, sugars, and ions) across cell membranes (234,235). Members of this group of proteins are most similar in the hydrophilic region containing an ATP-binding site (5,236). Therefore, by comparison with this family of proteins, it was originally proposed that CFTR may function as an ATP-dependent transporter, possibly exporting molecules across cell membranes (5).

Expression of CFTR, or portions of CFTR, demonstrates that most of the initial predictions of the topology and functional domains of CFTR were quite accurate. Localization of CFTR in vivo with antibodies is consistent with its presence in the apical cell membrane (205,210,216,237). Insertion of novel N-glycosylation sites indicates that the 12 putative hydrophobic segments traverse the cell membrane (238) (Figure 58-3). The putative NBDs both bind ATP, and the first domain (NBD1) hydrolyzes ATP (239–245). Finally, phosphorylation of several residues in the R domain by protein kinase A (PKA) plays an important role in regulating CFTR function (246,247).

**58.3.2.2 CFTR Is a cAMP-Regulated Chloride Channel.** Although the overall structure of CFTR is similar to ABC transporters, experimental evidence convincingly demonstrates that it functions as a chloride channel (248–250). Expression of CFTR resulted in the appearance of novel cAMP-stimulated chloride secretion in a variety of cells derived from non-epithelial tissue that do not have cAMP-activated chloride channels (251,252). Furthermore, the magnitude of this secretion was correlated in a linear fashion with the amount of CFTR protein present (251,252). Similar results were obtained by heterologous expression of CFTR in mouse cells and *Xenopus* oocytes (253–256). Second, reconstitution of CFTR into planar lipid bilayers was associated with cAMP-regulated chloride channel activity. The protein was initially purified from Sf9 insect cells and its identity confirmed by immunoblotting, isoelectric point analysis, amino-terminal sequencing, and amino acid composition (257). Following reconstitution into phospholipid vesicles, cAMP-activated channels were identified with properties virtually identical to chloride channels in Sf9 and hamster (CHO) cells transfected with CFTR and human colonic epithelial (T84) cells that normally express CFTR (257). A third line of evidence is derived from functional studies of mutated CFTR. Based on the hypothesis that charged residues in membrane-spanning regions play

**FIGURE 58-3** Structural and Functional Domains of CFTR. CFTR is composed of two TMDs (TMD1 and TMD2) each containing six hydrophobic segments inserted into the cell membrane, two intracellular NBDs (NBD1 and NBD2) that interact with ATP and an intracellular regulatory (R) domain that is phosphorylated by protein kinase A. The fourth extracellular loop has two sites for asparagine-linked glycosylation. Residue numbers are shown.

an important role in ion conductivity of the channel, Anderson and colleagues changed four of six evolutionarily conserved basic amino acids in putative transmembrane segments of CFTR (258). One mutation, lysine to glutamic acid at codon 335 (K335E), caused changes in the anionic permeability and ion conductivity of CFTR. The preference of wild-type CFTR for chloride over iodide was reversed in the mutant channel (258). Since numerous other properties of CFTR were unaltered, it was suggested that lysine at position 335 was critical for determining anion selectivity of CFTR and infers that CFTR itself forms a chloride channel. The demonstration that disease-producing mutations affect the chloride conductance properties associated with CFTR probably provided the most convincing argument that CFTR is a channel. Alterations found in patients with milder pancreatic disease (R117H, R334W and R347P) reduce but do not abolish the conductance of CFTR bearing these mutations (259,260).

Which regions of CFTR form the channel pore? Several different but complementary approaches have progressively narrowed the critical region of CFTR involved in ion conduction. Deletion of a portion of the R domain produced a functional CFTR mutant with altered regulation (261). Channel function was lost upon removal of the entire R domain and upon deletion of NBD1, NBD2, or both NBDs (262). Truncation of the carboxy-terminus up to, but not including, NBD2 was associated with chloride channel properties similar to wild-type CFTR (262). These results suggested that several domains of CFTR had to be intact to create a functional channel. Expression of the amino-terminal half of CFTR containing TMD1, NBD1, and the R domain generated cAMP-regulated chloride conductances (263). The anion selectivity and the current-voltage relationship of the channel formed by this CFTR mutant were similar to wild-type. However, the magnitude of current was significantly lower for the half-molecule and its regulation was also altered (263). The last transmembrane segment in the second half of CFTR (TM12) may also play a role in channel formation (264). Amino acids in the first part of CFTR have been removed and shown not to be involved in channel formation. Mutant CFTR with the first four transmembrane segments of TMD1 deleted produces a functional channel with ion selectivity that is identical to wild-type (265). These truncation studies indicate that the fifth and sixth transmembrane segments (TM5 and TM6) in TMD1, NBD1, and the R domain are required to form a chloride-selective channel. Mutation of individual amino acids in TM6, particularly the arginine residue at codon 347, altered the conductance properties of the CFTR channel (264,266), suggesting that TM6 is intimately associated with the channel pore. The importance of TM6 in channel formation has been confirmed by the scanning-cysteine-accessibility method (267). Regulation of channel opening is mediated by ATP binding to each NBD and dimerization of these domains.

Hydrolysis of ATP bound to the second NBD appears to facilitate channel closing (268–270).

**58.3.2.3 CFTR Is a Regulator of Other Proteins Involved in Ion Transport.** It has been shown that CFTR is capable of regulating the function a number of proteins, an outwardly rectifying chloride channel (ORCC), an amiloride-sensitive epithelial  $\text{Na}^+$  channel (ENaC), an inwardly rectifying ATP-sensitive renal potassium channel (ROMK2), and members of the SLC26 family of anion transporters (271–276). There is an interesting history behind the discovery that CFTR regulates a separate chloride channel. In 1983, Quinton made the seminal discovery that sweat duct cells of CF patients had low permeability to chloride (277). Following this observation, electrophysiologic studies implicated abnormal regulation of an outwardly rectifying, epithelial chloride channel as the molecular defect in CF (278–281). The channel characterized in these studies was present in membranes of CF cells but failed to activate upon the addition of either protein kinases A or C (282,283). Following the cloning and characterization of CFTR, it was realized that the abnormally functioning ORCC in CF tissues was not CFTR (284,285). An intimate relationship between CFTR and ORCC was illustrated by expression of CFTR in an epithelial cell line derived from a CF patient. PKA-activation of ORCC was recovered, and regulation of ORCC in complemented cells was similar to normal epithelial cell lines (271,286). This discovery implied that either CFTR formed more than one type of channel or that the ORCC was a separate entity (Figure 58-4).

The molecular identity of ORCCs and the mechanism by which CFTR regulates the ORCC have not been resolved. Several independent observations implicate ATP as the mediator between CFTR and ORCC.

**FIGURE 58-4** CFTR Regulation of the Outwardly Rectifying Chloride Channel (ORCC) and the Epithelial Sodium Channel (ENaC) in Secretory Epithelia. CFTR is activated by phosphorylation of the R domain and ATP interaction with the NBDs. Activation of CFTR has a positive regulatory effect upon the ORCC and a negative regulatory effect upon ENaC. The former is postulated to occur by an autocrine mechanism involving CFTR-mediated export of ATP. The mechanism underlying the interaction between CFTR and ENaC is unknown. The direction of chloride and sodium movement through these channels depends upon the intracellular and extracellular concentrations of each ion and the membrane potential (see Figure 62-4).

Stutts and colleagues demonstrated that extracellular ATP increased the amount of time that ORCCs in epithelial cells were open. It was hypothesized that this interaction occurred via a purinergic receptor (P<sub>2U</sub>) (287,288). Concurrently, it was shown that CFTR is permeable to ATP in addition to chloride (289). These observations have been unified into a single mechanism by which CFTR regulates the ORCC via an autocrine mechanism involving ATP (290) (Figure 58-4). This process may be mediated by sequences in the first NBD and/or the R domain (291,292). It had been proposed that an isoform of the voltage-gated channel 3 (CIC-3B) generates ORCC-like currents (293). However, studies of colocalization and interaction with CFTR have been inconsistent (294). Thus, the identity of ORCC remains a mystery. Other proteins, such as SLC26A9, that contribute to chloride conductance in secretory epithelia also appear to be regulated by CFTR (295).

A regulatory relationship between CFTR and the amiloride-sensitive ENaC has also been demonstrated (Figure 58-4). Increased absorption of sodium by respiratory epithelia compounds the difficulty of hydrating mucus secretions in CF patients (296,297). This electrophysiologic abnormality has been attributed to CFTR dysfunction; nasal epithelial cells from “CF mice” demonstrate increased Na<sup>+</sup> absorption (298) and heterologous expression of CFTR in primary CF airway cells normalizes Na<sup>+</sup> absorption (299). Cloning of the three subunits that form the amiloride-sensitive ENaC enabled coexpression studies confirming the interaction between CFTR and this separate channel (272,300). Activated CFTR exerts a negative regulatory effect upon the ENaC, decreasing sodium absorption (Figure 58-4). On the other hand, studies of sweat duct cells indicate that CFTR has a positive regulatory effect upon ENaC (301). The mechanism underlying the interaction between CFTR and ENaC is not certain although there is evidence that the first NBD of CFTR (302) and proteolytic mechanisms (303) are involved. Interestingly, the first nucleotide binding domain of CFTR appears to be required for regulation of the potassium channel ROMK2 (304). Finally, it has been suggested that CFTR modulates bicarbonate secretion by regulation of chloride–bicarbonate exchangers (305–307). This hypothesis is attractive since bicarbonate secretion is impaired in CF cells (308,309). Members of the SLC26 family of chloride–bicarbonate exchangers have been shown to interact and regulate CFTR (276,276).

**58.3.2.4 Other Proposed Functions of CFTR.** In addition to functioning as a chloride channel and as a regulator of separate ion channels and transporters, several other functions have been proposed for CFTR. CFTR appears to play a role in the regulation of volume-regulated anion channels and gap junction channels (310,311). Other proposed functions of CFTR include sensor for intracellular ATP levels (312), conductor of a variety of small solutes and water across cell membranes

(313), and facilitator of acidification of intracellular organelles (314,315). Loss of these properties could explain a number of metabolic derangements in CF cells. However, insufficient corroborating evidence is available to assign these functions to CFTR.

**58.3.2.5 CFTR Interacts with Cytosolic Proteins.** The amino and carboxy terminal regions of CFTR interact with a number of proteins (316). Interaction of the amino terminus of CFTR with syntaxin 1A mediates chloride channel activity and regulates trafficking of CFTR (317–319). The carboxy terminus of CFTR contains sequences that influence stability (320,321) and facilitate entry into clathrin-coated vesicles, recycling from the plasma membrane, and localization in polarized epithelium (322–324). Several lines of evidence suggest that CFTR physically interacts with a macromolecular complex at the apical membrane via a PDZ domain that augments CFTR function, and links CFTR to the cytoskeleton and metabolic state of the cell (see Ref. (325) for a comprehensive review). Components in the macromolecular complex may include several of the aforementioned proteins regulated by CFTR (e.g., SLKC26 and RomK) (276,326) as well as upstream mediators of CFTR activation such as the  $\beta$  adrenergic receptor and phosphodiesterase 4D (327,328).

**58.3.2.6 Abnormal CFTR Function Causes the Epithelial Ion Transport Defect in Patients with CF.** Abnormal transport of sodium and chloride in epithelial cells lining the airways of the lungs and in the sweat glands of CF patients is the biochemical defect in CF (277,329). A number of studies have shown that provision of normal CFTR to epithelial cells derived from CF patients revert cellular phenotypes to normal. Using a retroviral vector, Drumm and colleagues transferred the normal CFTR cDNA to a pancreatic adenocarcinoma cell line from a CF patient (CFPAC-1) (330). Stimulation of transfected cells with cAMP or forskolin (which increases intracellular cAMP) produced chloride secretion that was absent in cells transfected with the virus alone. Similarly, expression of wild-type CFTR in CF airway cells also corrected the ion transport defect (331). This correction did not occur when mutant CFTR containing the common CF mutation  $\Delta F508$  (described below) was used. Furthermore, reduction in endogenous CFTR levels is associated with loss of cAMP-activated chloride transport in epithelial cells. This has been achieved by decreasing CFTR mRNA transcription using a phorbol ester or interfering with translation with antisense oligonucleotides (332–334). These studies confirmed that CFTR plays a central role in the chloride transport that is defective in cells of CF patients. More recently, the development of a porcine model of CF has led to a re-evaluation of the role of aberrant sodium transport at the earliest stages of CF (335). Studies of primary airway cells from humans with CF suggest that the alteration in currents caused by the sodium channel inhibitor amiloride reflects changes in chloride rather than sodium transport (336).

Although a great deal is known at the molecular and cellular level, the mechanism by which CFTR dysfunction leads to disease manifestation at the organ level is poorly understood. This is particularly true for pulmonary disease, the primary cause of morbidity and mortality in CF. Indeed, a major debate in CF research is whether the underlying pathophysiology in CF is due to a loss of electrolyte and fluid secretion or absorption, or a combination of both (Figure 58-5) (337). Attention was focused upon this issue after publication of a provocative study by Smith, Welsh, and colleagues. These investigators suggest that high salt concentrations in the airway surface liquid (ASL) of CF patients inhibited bacterial killing mediated by antimicrobial peptides (338).

Shortly thereafter,  $\beta$ -defensin-1, a human antimicrobial peptide present in respiratory epithelia, was shown to have reduced anti-pseudomonas activity in high salt solutions (339). However, the “high salt” concept ran counter to the concept that epithelial cells in the airways are highly permeant to water and that sodium absorption is increased in CF patients (297,329,340). The latter “low volume” theory implied that the ionic composition of ASL should not differ between normals and CF, but the volume of ASL would be reduced leading to altered viscosity of ASL and impaired clearance of pulmonary secretions. Measurements of ion concentrations in ASL have been difficult, and results comparing CF and normal have been conflicting (341–343). However, there

### (A) Secretion

### (B)

### (C) Absorption

### (D)

**FIGURE 58-5** Simplified Model of Electrolyte and Water Transport across Normal and Cystic Fibrosis Airway Epithelia. A. Secretion. The top panels demonstrate the process of secretion in normal and CF airway cells. The  $\text{NaK}_2\text{Cl}$  co-transporter (shaded oval) pumps chloride from the submucosa into the cell. Sodium and potassium that are transported with chloride exit via the  $\text{NaK}$  ATPase (open circle) and by the basolateral  $\text{K}^+$  channel (filled rectangles). The net result is an increase in the intracellular concentration of chloride. Binding of a  $\beta$  agonist to receptors located on basolateral membranes increases the intracellular levels of cAMP and activated PKA. Phosphorylation of CFTR by PKA causes activation of CFTR and ORCC, and chloride, driven by its concentration gradient, flows out the cell across the apical membrane. Other apical membrane chloride channels also participate in chloride transport out of the cell. Sodium follows the electrochemical gradient created by chloride ion secretion and flows from the submucosa to the lumen via a paracellular pathway. A minor fraction of sodium is reabsorbed via ENaC (downregulated by activated CFTR). The movement of sodium and chloride ions from submucosa to the lumen drives water secretion across the epithelial cell layer. In CF cells, CFTR function is absent leading to severely reduced chloride transport into the lumen, hyperabsorption of sodium due to increased activity of ENaC, and impaired water secretion. B. Absorption. The two bottom panels illustrate the process of absorption in normal and CF airway cells. Activation of CFTR permits chloride movement from the lumen, across the cell and into the submucosa. The “low volume” hypothesis of CF pathogenesis proposes that in the absence of functional CFTR, sodium is hyperabsorbed due to loss of ENaC regulation. Chloride is also hyperabsorbed through transcellular and paracellular pathways. Due to the presence of water channels in airway epithelial cells, the increased absorption of sodium and chloride into the submucosa leads to excessive water absorption. The movement of isotonic fluid into the cell layer reduces the volume of the airway surface liquid.

is substantial evidence that the salt concentration of ASL from CF patients and normals is similar and that altered ASL properties affect clearance of airway secretions in CF patients (344–346). Continued investigation of the pathophysiology of CF airway disease is likely to reap therapeutic dividends (347–349).

### 58.3.3 Mutations in the *CFTR* Gene

**58.3.3.1 Nature of Mutations.** Over 1800 putative disease-causing mutations have been reported to the CF Mutation Database (<http://www.genet.sickkids.on.ca/PicturePage.html>). The majority of these mutations involve one or a few single nucleotides; about 40% of the reported mutations cause a change in the amino acid and are termed missense, 8.5% change the amino acid to a termination codon and are termed nonsense, and approximately 12% alter nucleotides known to be crucial to the proper splicing of RNA into messenger RNA. Most of the remaining point mutations involve an insertion or deletion of nucleotides that changes the reading frame of the mRNA and usually introducing a premature termination signal. About 2% of mutations are exonic deletions that leave the reading frame intact. Insertions or deletions involving many nucleotides from one or more *CFTR* exons account for nearly 3% of CF alleles. Several recur in select populations (350–353).

Numerous examples of multiple mutations in the same *CFTR* gene have been published (354–361). In at least three cases, the two alterations appear to work in concert to alter the phenotype produced (354,357,361). Putative disease-associated mutations in the start-site for translation have also been identified (362,363). Several deleterious mutations of the *CFTR* promoter have been reported and correlated with altered *CFTR* RNA expression (364,365).

Over 200 of the mutations reported in *CFTR* appear to be “benign” polymorphisms that do not cause CF ([www.genet.sickkids.on.ca/](http://www.genet.sickkids.on.ca/)). Most notable is the observation that the phenylalanine residue at codon 508 can be changed to cysteine and the isoleucines at codon 506 or 507 can be changed to valine without apparent effect (366). Furthermore, these three missense changes do not cause CF when found *in trans* with a known CF-causing mutation such as F508del. However, there is evidence that mutations that do not change an amino acid can have deleterious effects upon RNA processing. These “synonymous” mutations alter regions that interact with splicing factors that enhance or suppress inclusion of exons in the mature RNA (367,368). Furthermore, population analysis indicates that it is difficult to distinguish rare exonic variants of deleterious effect from those that are benign (369). Thus, variations in *CFTR* exons occurring in a clinical context consistent with CF have to be interpreted with caution, even if there is no predicted change in the encoded amino acid. Numerous DNA sequence variants in the non-coding region of the

*CFTR* gene have also been reported to the Consortium. The majority are in introns within 100 bp of the splice sites. While most of these non-coding variants are likely to have no effect, some may affect splicing by activating cryptic splice sites (370) or by affecting binding of splicing factors as noted above. Two intronic point mutations distant from the splice acceptor and donor sites have been well characterized. One occurs in intron 19, 10 kb from the 3' end of exon 19 while the other is 1.6 kb from the end of exon 11 (43,45). Both activate cryptic splice donor sites and cause the inclusion of novel sequence into the *CFTR* mRNA transcripts.

The advent of nationwide newborn screening has led to a reassessment of the utility of DNA testing to diagnose CF (38). To assess the disease-causing liability of CF mutations, the Clinical and Functional Translation of *CFTR* (CFTR2) project was initiated with support from the CF Foundation in the United States (371). The ambitious goal of the project is to annotate the disease implications of all *CFTR* mutations and to provide this information on a public website. Release of the first version of CFTR2 is imminent.

**58.3.3.2 Frequency and Distribution of Mutations.** One mutation has been found to occur in about 70% of *CFTR* genes from CF patients (29). The mutation is a deletion of three nucleotides which causes the omission of a phenylalanine residue at position 508 in the protein. The mutation has been named F508del, F is the single-letter code for a phenylalanine residue, 508 denotes the codon affected, and del is shorthand for deletion. Although this is the most common CF mutation, its frequency varies considerably among human populations. The highest frequency has been found in Northern European populations where it accounts for 75–88% of CF alleles. The frequency drops to 50–60% in Southern European populations and even lower in the Ashkenazi and African-Americans (29). In Europe, the frequency of  $\Delta$ F508 increases along a southeast to northwest gradient (29,372).

Apart from F508del, a subset of approximately 20 mutations occur with a frequency greater than 0.1% in mixed European Caucasian populations (Table 58-3). In ethnically discrete populations, such as Ashkenazi Jews, Hutterites in Alberta Canada, French-Canadians in the Saguenay-Lac St. Jean region of Quebec, and Native Americans, a few mutations account for nearly 100% of CF alleles (Table 58-4). It has been surmised that carriers of these mutations must have been among the founders of these ethnic groups. Marriages within these groups then maintained these mutations at higher frequencies than observed in the general populations. Screening with the appropriate panel of CF alleles can achieve detection rates over 90% in geographically defined populations (Table 58-4). However, a very large number of mutations (>300) have to be screened to achieve detection above 90% in diverse populations such as France (373). Over 30 mutations occur at high frequency only in select

Spain	75	90	53.2	(771)

populations (374). Examples include the Y122X mutation, which accounts for 48% of CF alleles in Reunion Island but is rare elsewhere (375). The remainder of the mutations reported to the CF Mutation Database is rare, occurring on only one or a few chromosomes.

Mutations in the CFTR genes of non-Caucasian CF patients have also been reported. Individuals of African descent living in the United States have been extensively studied. Similar to Caucasians, ΔF508 is the most common mutation (48%) in this population probably due to

admixture (376). Several of the African-American mutations appear to be of native African origin (36,376,377). A study of 82 African-Americans identified putative deleterious CF mutations in 96% of patients and discovered a subset of eight common “African-American” mutations accounted for 23% of CF alleles (376). For example, the second most common mutation in African-Americans, 3120 + 1G → A was found in four of six CF chromosomes from native Africans (377). Three mutations have been found to account for all CF alleles in the Zunis tribe of native Americans (378,379). Interestingly, one of these mutations was originally reported in Northern Italian Caucasians. A small study of Asian CF chromosomes from Japan, Korea, Thailand, and Vietnam revealed five different mutations, one in homozygosity (380). A different mutation, 1898 + 5G → T, was found on 3 of 10 chromosomes in Chinese patients living in Taiwan (381). None of these Asian mutations was previously reported in Caucasian patients. Together, these studies demonstrate that non-Caucasian populations have CF mutations that are unique as well as those acquired by admixture with Caucasians.

To determine the possible origin of disease-causing mutations, DNA polymorphism haplotypes created by CF-linked markers have been analyzed on chromosomes bearing some of the more common CF gene mutations. Several studies demonstrate that the predominant mutation, F508del, is almost exclusively associated with one marker haplotype (6,382,383). This strongly suggests that this common mutation is of a single origin. The timing of this mutation in human evolution is a matter of some debate with estimates ranging from 3000 to 53,000 years ago (164,384). Haplotype analysis indicates that mutations G551D and G542X also have single origins (385). The frequency of these less common mutations also varies among populations. The G551D mutation is found on 5% of CF chromosomes from Scottish patients, 3% of CF chromosomes in North American Caucasians, but rarely on CF chromosomes from patients in Southern Europe (386,387). The nonsense mutation, G542X, appears to occur in most populations and varies between 1% of CF chromosomes from African-American patients to 12% of chromosomes from Ashkenazi Jewish patients (26,355). These differences in population distribution may reflect differences in the timing of each mutation during human evolution, differences in selective pressures exerted upon each mutation, or both. One mutation, R553X, is associated with a significantly different haplotype in African-Americans than that observed in Northern Europeans. Since this mutation occurs at a region of DNA vulnerable to mutation (a CG dinucleotide), most likely this mutation has arisen several times during human evolution on chromosomes with different haplotypes (385). Several other CF mutations have recurred during human evolution including R117H, R334W, R347P, R1162X, and 3849 + 10 kb C → T (357,388).

### 58.3.4 Effects of CF Mutations on CFTR Function

Understanding the consequences of mutations upon function provides a starting point for dissecting the complicated pathway from the gene defect to pathology of the organism, and opens important avenues for novel therapeutic approaches to CF. The effects of only a small fraction of the over 1800 mutations upon CFTR function have been assessed. In most cases, the effect of a mutation has been inferred from studies of mutant CFTR overexpressed in immortalized cells. A few studies have analyzed mutated CFTR in primary cells or native tissue. Therefore, our understanding of the consequences of mutations upon CFTR function is still evolving. However, a clear picture has been drawn for the common mutation F508del and several of the less common mutations. The effects of mutations upon CFTR function have been grouped into classes (389). The number of mutation classes differs somewhat among publications (149,390) and the originally proposed five classes of mutations has high utility since it correlates well with disease severity (133). Mutations in Class I, II, and III generally have severe effects upon CFTR synthesis or function and are associated with more severe forms of the disease while those in Class IV and above can have moderate effects resulting in milder forms of the disease.

**58.3.4.1 Mutations that Alter RNA Processing that Severely Reduce or Cause Loss of Protein Synthesis (Class I).** About one half of the mutations reported to the CF Mutation Database are predicted to affect RNA processing. Several of these mutations are less common than F508del but not rare in Caucasians (Table 58-3). Some introduce a premature signal for termination of translation. This group includes those that substitute an amino acid with a termination signal (nonsense mutation), those that delete or insert one or more nucleotides that are not multiples of 3 (frameshift mutation), and those that cause aberrant exon splicing (splice-site mutation). The common effect of these mutations is severe reduction in mRNA transcript level from the gene containing the alteration due to a phenomenon known as nonsense-mediated mRNA decay (391–396). The mechanism underlying this process is conserved from yeast to mammals and it plays a key role in regulating gene expression (397). The effect of the W1282X nonsense mutation (most common mutation in Ashkenazi CF patients) is not clear since two studies report severe reduction and one reports no significant reduction in mRNA levels (392,396,398). A nonsense mutation that is not associated with RNA decay is R1162X, an allele, common in Northern Italy (396,399). Severe reduction in transcript levels would be expected to cause a corresponding reduction or more likely absence of the CFTR protein. This has been demonstrated for patients carrying two nonsense mutations (400,401).

One nonsense mutation in *CFTR* (E831X) was found to be unexpectedly associated with mild PS CF (402). Further investigation revealed that the mutation occurred near a 5' splice site and that alternative splicing enabled the production of a RNA transcript free of the premature termination codon (PTC). Loss of the three nucleotides encoding the PTC caused omission of the glutamic acid at codon 831. However, CFTR missing this residue was properly folded, trafficked to the cell membrane, and partially functional. Retention of some CFTR function appears to explain the mild phenotype noted in individuals with two copies of E831X (402).

Premature termination mutations can also cause exon skipping and aberrant RNA splicing. Three nonsense mutations (E60X, R75X, and R553X) have been reported to cause skipping of the exon in which they reside (396,403). In each case, loss of the exon causes a frameshift and introduction of additional PTCs. The nonsense mutation E92X, caused by an alteration in the first nucleotide of exon 4, is associated with exon 4 skipping and tissue-specific aberrant splicing (404). In nasal epithelial cells, a novel exon is added to the full-length *CFTR* mRNA. The novel exon, however, contains in-frame termination codons that would be expected to lead to loss of the mRNA with the novel exon.

Splice-site mutations affect RNA processing by altering the composition of the *CFTR* messenger RNA. Two examples are 621 + 1G → T and 711 + 1G → T that account for 0.7% and 0.1% of mutant CF alleles, respectively (Table 58-3). The first mutation alters the splice-site immediately following exon 4 of *CFTR* and produces two aberrantly spliced RNAs, both of which retain an open reading frame (405,406). The 711 + 1G → T mutation changes the splice-site following exon 5 causes skipping of the entire exon. Since the number of nucleotides forming exon 5 is a multiple of 3, the loss of this exon also leaves the reading frame intact (405). These aberrant transcripts may be translated into protein products that may be unstable, non-functional, or partially functional. Determining which of these possibilities occur usually requires protein expression and analysis.

**58.3.4.2 Mutations that Cause Defective CFTR Maturation (Class II).** In a seminal paper, Smith and colleagues suggested that the majority of CF mutations that change a single amino acid caused abnormal processing of the mutant protein (407). Indeed, the study of CFTR processing has emphasized the critical role that cellular quality control mechanisms play in distinguishing misfolded mutant protein (408,409). For example, two mutations, F508del and the most common missense mutation G551D (~1.6% worldwide) had very different effects when transiently expressed in heterologous cells. CFTR bearing  $\Delta$ F508 was incompletely glycosylated suggesting that it was being improperly processed (407). On the other hand, CFTR bearing G551D was fully glycosylated and predicted to be properly processed. Localization of mutant CFTR by immunocytochemical stains of

sweat glands from CF patients showed that  $\Delta$ F508-CFTR was contained within the cytoplasm in a perinuclear distribution consistent with abnormal processing, while G551D-CFTR localized to the cell membrane similar to properly processed wild-type CFTR (210,401). Whether F508del-CFTR is misprocessed in a tissue-specific manner has been a matter of debate (410).

Further studies have shown that  $\Delta$ F508 is a temperature-sensitive mutation (411). CFTR bearing  $\Delta$ F508 can be found in the cell membrane when expressed in cells growing at lower temperatures (25 °C instead of 37 °C) such as *Xenopus* oocytes and cells from an insect (fall armyworm) (251,253). In fact, F508del-CFTR isolated from the insect cells can function as a cAMP-dependent chloride channel although its stability appears to be reduced (412,413). A variety of other CF missense mutations have been shown to interfere with CFTR processing (414–416). The missense mutation G480C has been found in three African-American patients with pancreatic insufficiency. CFTR bearing this mutation functioned similar to wild-type CFTR in *Xenopus* oocytes at 19 °C but was improperly processed in mammalian cells at 37 °C (417). Two mutations A455E and P574H associated with a milder form of pancreatic disease were shown to alter CFTR processing. However, some mature protein was synthesized that functioned similar to wild-type CFTR (418).

**58.3.4.3 Mutations Associated with Partially Functional CFTR (Classes III and IV).** If mutant CFTR protein is trafficked to the cell membrane, the possibility exists that the protein may retain some function. Determination of the amount of residual function can provide considerable insight into the role of CFTR dysfunction in CF pathophysiology. Structure/function studies of select CF missense mutations indicate that one or more aspects of CFTR function can be affected. Two mutations of the same amino acid in the first ATP-binding domain (G551S and G551D) alter the activation of CFTR (Figure 58-6; Class III) (255). High levels of stimulation achieved by using non-hydrolyzable forms of cAMP (CPT-cAMP) and a potent phosphodiesterase inhibitor (IBMX) can activate these mutant molecules (255,256). Newer CFTR potentiators selected to activate CFTR bearing gating mutations such as G551D have shown considerable therapeutic promise (419,420).

Missense mutations in cytoplasmic loops of the TMDs appear to affect CFTR channel regulation (414,415,421,422). Other mutations affect conductance through the CFTR chloride channel (Figure 58-6; Class IV). Five mutations (R117H, R334W, R347P, R347H and P574H) associated with non-classic forms of CF have been extensively evaluated. In each case, the mutant CFTR was shown to be functional although the degree of retained function varied considerably (259,260,266,423). The effects of the R347P and R347H mutations were primarily confined to changes in ion flow through the CFTR chloride channel (260,266) while the

**FIGURE 58-6** The Cellular Consequences of Five Classes of Mutations.

P574H mutation selectively altered the duration of channel opening (418,423). However, the R117H mutation altered the rate of ion flow through the CFTR channel and reduced the amount of time the channel remained open (259,260). The observation that two properties of the channel were altered by a single mutation suggests that the region of CFTR that forms the channel and the region that regulates the chloride channel may overlap. Conversely, this mutation may have a pervasive allosteric effect on the two functional domains of CFTR.

**58.3.4.4 Mutations Associated with Reduced Levels of Wild-Type CFTR (Class V).** Some splice-site mutations have an intermediate effect upon splicing that permits the production of a low level of properly spliced mRNA. An excellent example is the 3849 + 10kbC → T mutation. This mutation activates a cryptic splice donor site in intron 19 causing the inclusion of a novel 84 basepair exon into CFTR mRNA transcripts (45). This insertion does not alter the reading frame but would be predicted to encode a truncated protein. However, the mutation does not alter all transcripts produced by a CFTR gene carrying the 3849 + 10kbC → T mutation. The 3849 + 10kbC → T mutation is found on 0.2% of CF chromosomes worldwide and is relatively common in the Ashkenazi Jewish population (4% of CF alleles) (26,374). About 8% of nasal epithelial CFTR mRNA transcripts are properly spliced in a patient homozygous for this mutation (45) and would be expected to produce a small amount of wild-type CFTR protein. Therefore, some splice-site mutations are predicted to reduce the amount of wild-type CFTR protein produced.

**58.3.4.5 Mutations with Other Effects.** Some mutations have been shown to affect the ability of CFTR to regulate other proteins. For example, CFTR bearing G551D, a mutation that causes pancreatic insufficiency and severe pulmonary disease, retains some chloride channel function but cannot activate the ORCC (424). However, A455E, a mutation associated with mild lung disease, permits CFTR to function as a chloride channel and as a regulator of the ORCC. These results indicate

that the two functions of CFTR are separately mutable and suggest that alteration of the regulatory function of CFTR may have some consequence upon phenotype (424). Interestingly, CFTR regulation of the ENaC and of the inwardly rectifying potassium channel ROMK2 is also altered by the G551D mutation (304,425,426). Analysis of select disease-associated missense mutations in other regions of CFTR did not show altered regulation of the ORCC (292). Thus, one region of CFTR may be essential for its regulatory function. Mutations have also been shown to affect CFTR localization in polarized epithelia. Nonsense mutations in the last CFTR exon such as S1455X produce transcripts that escape nonsense-mediated mRNA decay (427). These transcripts are predicted to encode truncated forms of CFTR that are missing regions that mediate efficient apical retention of CFTR (428–431). Other mutations have been reported that create a novel internalization signal that reduces cell surface CFTR (432).

**58.3.4.6 Correlating CFTR Function and CF Phenotype.** Our understanding of this relationship falls into three groups: CFTR that is absent or degraded (Class I and II), abnormally functioning (Class III and IV), or reduced (Class V). Complete loss of functional CFTR, whether due to absence of the mRNA, defective protein processing, or inactivation by a mutation, results in classic CF: pancreatic exocrine dysfunction, elevated sweat electrolytes, absence of the vas deferens, and chronic life-limiting pulmonary disease. Mutations that alter but do not abolish the function of CFTR can give rise to mild CF. For example, residual CFTR-mediated chloride secretion in rectal epithelia correlates with CFTR genotype and with later onset of disease, higher frequency of pancreatic sufficiency, and milder lung disease (433). Changes in the conduction properties of the channel are generally associated with less severe phenotypes (e.g., R117H, R334W, R347P) (260). In some cases, the amount of partially functional protein is correlated with the development and severity of lung disease (e.g., R117H and P574H) (357,418,423). Reduction in the level of normally functioning CFTR due to mRNA splicing defects generally produces non-classic forms of CF (45,434). Thus, the degree of residual CFTR function appears to correlate with severity of phenotype.

### 58.3.5 Relationship Between CFTR Genotype and Phenotype

The section above described our current understanding of the effect of disease-associated mutations upon CFTR function, a fundamental aspect of pathogenesis. Extensive studies have also been performed to determine the degree to which CFTR genotype correlates with the features that compose the CF phenotype. Two general approaches have been taken to assess the association between CFTR genotype and phenotype. One method is to determine severity of disease in patients selected by

genotype, while the second involves determining genotypes in patients with similar degrees of illness. From these studies it is apparent that some features of the disease are correlated with genotype. CFTR genotype influences severity of pancreatic disease, degree of sweat chloride abnormality, and age of onset of disease (Table 58-5). For pulmonary disease, an association exists but is confounded by other variables including genetic background and environment. Complications such as MI and pancreatitis are influenced by the nature of the CF mutation (435–437).

**58.3.5.1 CFTR Genotypes Associated with Classic CF.** The commonness of the F508del mutation has facilitated a thorough analysis of the phenotype associated with this mutation. As expected, homozygosity for F508del is associated with the classic form of CF including pancreatic insufficiency, significantly elevated sweat chloride levels, and chronic lung disease (89,438) Pulmonary disease in F508del homozygotes can vary from mild to very severe (85,89,438,439). Collaborative reports

have been published comparing the phenotypes of compound heterozygotes carrying one of the less common CF mutation and F508del with patients homozygous for F508del. Patients heterozygous for G551D/ΔF508 were clinically indistinguishable from ΔF508 homozygotes, apart from a decreased risk of MI (435,440). Interestingly, a higher rate of MI was observed in a small group of patients with the G542X/ΔF508 genotype (99).

Shortly after the cloning of the CFTR gene, two patients with mild pulmonary disease were discovered carrying nonsense mutations in each CFTR gene (441). This observation indicated that the CFTR protein was not essential for life and suggested that the absence of the CFTR protein may be less harmful than the presence of mutant protein. Subsequent studies on larger groups of patients analyzing a nonsense mutation common in the Ashkenazi population (W1282X) indicated that individuals homozygous for this mutation had disease that was very similar to that observed in individuals carrying this mutation paired with ΔF508 or with individuals

homozygous for  $\Delta F508$  (442). Studies of other nonsense mutations such as R1162X and R553X have revealed subtle phenotypic differences from  $\Delta F508$  homozygotes (354,443,444). A collaborative study involving 32 laboratories worldwide studied this issue in a large group of patients carrying  $\Delta F508$  compounded with the nonsense mutations G542X, R553X, or W1282X and 18 patients carrying nonsense mutations in each gene (Table 58-5). No significant differences were seen in the compound heterozygotes when compared to individuals homozygous for  $\Delta F508$  (89). These data indicate that nonsense mutations are generally associated with the same phenotype as observed in  $\Delta F508$  homozygotes, although at least one exception exists (see above).

**58.3.5.2 CFTR Genotypes and Severity of CF Lung Disease.** Pulmonary disease is the primary cause of morbidity and mortality in CF patients. Thus, the relationship between CFTR mutations and lung disease severity has been of high importance in CF research. Studies of small numbers of monozygotic and dizygotic twins and siblings with CF indicated that genetic factors exist that influence pulmonary disease severity (439,445). Furthermore, pancreatic sufficiency appeared to be associated with improved respiratory function (84). Whether this was due to improved nutritional status or a direct consequence of the mutations carried by PS patients was unclear. However, initial genotype/phenotype studies did not show a correlation between mutations associated with a high likelihood of pancreatic sufficiency, such as R117H and R334W and severity of pulmonary disease (89,446). However, a mutation associated with pancreatic sufficiency, A455E, was shown to confer a milder pulmonary phenotype (Table 58-5). The commonness of this mutation in the Netherlands and in French-Canada facilitated the comparison of A455E heterozygotes with age and sex matched  $\Delta F508$  homozygotes from the same population (86,87). As with other studies of mutations associated with non-classic CF, patients with A455E were diagnosed later and most but not all were PS. Pulmonary function was improved in patients bearing A455E with FEV1 and forced vital capacity being significantly higher than in  $\Delta F508$  homozygotes. A455E patients also had lower rates of colonization with *P. aeruginosa* than their  $\Delta F508$  homozygote counterparts (86). A study of 267 German patients suggested an association between the type and location of CFTR mutations and predilection to chronic *P. aeruginosa* colonization (447). These studies raise the possibility that CFTR plays a role in bacterial colonization, an important aspect of lung pathophysiology in CF patients. Whether CFTR binds bacteria directly or is involved in the bacterial adherence properties of the respiratory epithelia is not clear (65,338,448–452).

**58.3.5.3 CFTR Genotypes Associated with Non-Classical CF.** Selection of patients with non-classic phenotypes and subsequent determination of mutations has provided considerable insight into the role of CFTR in CF pathogenesis. Prior to the identification of the

CFTR gene, pedigree analysis and DNA studies suggested that pancreatic status was determined by genetic factors (98,453). An extensive analysis of over 500 CF patients attending a single clinic in Toronto, Canada, provided evidence that genotype strongly influences pancreatic phenotype. Five mutations (R117H, R334W, R347P, A455E, and P574H) were found exclusively in PS patients (99). The influence of CFTR genotype upon severity of pancreatic disease has been confirmed by multicenter collaborative studies (Table 58-5). Analysis of 23 patients with the genotype R117H/ $\Delta F508$  revealed a high association with pancreatic sufficiency and provided evidence that R117H also influences the degree of sweat chloride abnormality and age of onset of disease (89). The association between mutation and pancreatic status is not absolute; however, since 3 of the 23 R117H/ $\Delta F508$  compound heterozygotes in the latter study were PI and 10 of the 396  $\Delta F508$  homozygotes were PS (89). Incomplete association with pancreatic sufficiency has been demonstrated for several other mutations (Table 58-5). For example, 9 of 15 patients carrying R334W combined with either  $\Delta F508$ ,  $\Delta I507$ , N1303K, G542X, or R1162X were PS (379). Therefore, these mutations can be associated with a milder pancreatic phenotype but other factors such as environment and genetic background must play a role in severity of pancreatic disease.

Family and DNA marker studies also suggested that patients with non-classic CF had different CFTR mutations than those with classic CF (454). Not unexpectedly, these patients carry splice mutations 3849 + 10 kb C  $\rightarrow$  T and 2789 + 5G  $\rightarrow$  T (45,434,455). A third mutation, a substitution of serine for glycine at codon 551 (G551S) was found in two older sisters with atypical CF (44). This mutation is interesting since a different substitution in the same amino acid (aspartic acid for glycine (G551D) causes classic PI CF. Other mutations associated with non-classic CF phenotypes in addition to those listed in Table 58-5 include P205S and L206W (456–458).

**58.3.5.4 Contribution of Modifier Genes to the CF Phenotype.** CF is a variable disorder, even among patients with identical CFTR genotypes (438). Case reports of patients who deviate from the clinical profile associated with a particular CFTR genotype emphasize the importance of other factors at the level of the individual patient (441,459–461). Several lines of evidence suggest that differences in genetic background accounts for a considerable fraction of disease variability, especially for the lungs (450,462,463). One of the most effective methods to determine the degree to which genes influence the occurrence of disease manifestations is to study related individuals. Siblings affected with CF demonstrate substantial similarity for a number of CF traits including MI, pancreatic status, and lung disease severity (%FEV1) (49,113,439,464,465). Although siblings share, on average, 50% of the variation in each autosomal gene, they also share similar environments (e.g., household, schooling, medical care). Dissection

of the genetic and environmental contribution to traits that are similar in siblings is facilitated by twin study. However, collection of data from sufficient numbers of affected twins requires large multicenter collaborative projects. The European CF Twin and Sibling Study demonstrated that a combined measure of body mass (weight for height percentage) and pulmonary disease showed greater similarity among 29 monozygous (MZ) twins than 12 dizygous (DZ) and 277 siblings pairs affected with CF. This difference was interpreted as evidence of genetic effect since MZ twins share 100% of their genes and DZ twins and sibling share 50% of their genes (466). A subsequent study of a larger number of twins and siblings was able to demonstrate that modifier genes play a substantial role in the variation in lung function as exhibited by robust estimates of heritability (0.54–1.0) (467). Affected MZ twins were also shown to have more similar measurements of chloride secretion across rectal and airway epithelia than DZ twins and siblings, indicating that modifier genes independent of CFTR influence this trait (468,469).

Identification of the genes and specific variant therein responsible for variation in traits under genetic control has been approached by candidate gene and genome-wide analysis (470,471). CF patients grouped according to disease status have been analyzed for significant differences in genotype frequencies in a number of biologically plausible candidate genes. Of the two dozen or so genes reported to show association with some aspect of CF disease severity, only a few have shown association in two or more independent samplings of CF patients. The latter is a key issue since population stratification can lead to false positive associations (472). Two genes, *transforming growth factor  $\beta$ 1* and *mannose binding lectin 2*, have stood the test of replication, although not all studies come to the same conclusions (473–478). Meta-analysis of published studies supports a role of *MBL2* in earlier acquisition of *P. aeruginosa*, lower lung function, and higher rate of lung transplantation (479). However, as more studies are performed in different CF populations, it is likely that true modifier genes will consistently demonstrate association, as noted for other complex traits (480).

Diabetes is a complication that increases in prevalence with age such that 40–50% of adults with CF are affected (481). Twin and sibling analysis revealed that risk for diabetes in CF is highly heritable with estimates approaching 1.0 (482). Evidence that a family history of type 2 diabetes increases risk for diabetes in a family member with CF (OR 3.1) suggested that the two forms of diabetes might have common genetic origins (108). Indeed, a single nucleotide polymorphism (SNP) near the *TCF7L2* gene that has been consistently associated with risk for type 2 diabetes demonstrates significant association with diabetes in CF (108). As over 40 genes have been associated with diabetes in the general population, it is likely that other risk genes will occur in common between CFRD and type 2 diabetes.

Liver disease provides a second example where a risk gene in the general population acts as a modifier of the same trait in CF. Hepatocellular disease is common in CF patients (see above). The *SERPINA1* Z variant that has been associated with risk for a variety of liver diseases in the general population was shown to dramatically modify risk for CF-related portal hypertension (483). Although the Z alleles are rare (~2%), the high risk of severe hepatic disease associated with this variant (OR ~ 5) provides a potentially useful clinical marker for this important complication.

While association studies provide a method to test candidate genes for influence upon phenotype, a different approach, akin to positional cloning, is required to find novel modifier genes. Using this approach in mice, Rozmahel and coworkers identified a locus in CF mice responsible for prolonged survival from fatal intestinal obstruction (484). Strain-specific differences in survival were used to map a locus on mouse chromosome 7 that was associated with survival. Additional loci for intestinal obstruction, body weight, and lung disease manifestations in CF mice have been reported (485–488). Studies of surviving mice suggest that a compensatory mechanism exists in their epithelial cells that facilitates sodium and chloride transport in the absence of CFTR (484). Since 15% of newborn CF patients exhibit a similar trait (neonatal intestinal obstruction or MI), a region of conserved synteny on human chromosome 19 was investigated for a modifying effect upon the MI phenotype. DNA markers from the human locus showed a high degree of allele sharing in siblings concordant for and a significantly lower than expected degree of allele sharing in sibs discordant for MI (489). These data suggested the existence of genetic variant (CFM1) independent of CFTR that contributes to the development of MI in humans. As of this time, a modifier gene has not been identified. Studies of twins in the U.S. CF Twin and Sibling Study have shown that the MI trait is primarily determined by genetic factors (119). Variable DNA markers from the CFM-1 region on chromosome 19 fail to demonstrate linkage of this region to MI in a larger number of CF siblings. However, suggestive linkage was observed to several chromosomal regions (119). Regional analysis of the chromosome 8p23.1 locus revealed significant association between MI and a haplotype composed of three SNPs located in intro 3 of the methionine sulfoxide reductase (*MSRA*) gene (490).

Genome-wide association and linkage methods have been applied to the search for genetic modifiers of lung function variation in CF. The *interferon-regulated developmental regulator-1* (*IFRD1*) was identified as a potential modifier of CF lung disease by performing genome-wide analysis on pooled CF patient with severe or mild lung disease. Promising candidates such as *IFRD1* were selected using hierarchical analysis. Replication of association of *IFRD1* variation and lung function in CF siblings and knock-out studies in mice supported

a modifier role for *IFRD1*. *IFRD1* modulates transcription during neutrophil differentiation, and loss of *IFRD1* leads to decreased effector function and reduced inflammation. Wright and colleagues identified two loci (chr 11p and chr 20q) that contained genetic modifiers of the pulmonary function measure FEV1 scaled as a percentile of severity among CF patients (491,492). The chr11 locus was identified by association and it is flanked by two genes (*APiP* and *EHF*) that have roles in apoptosis and lung development. The *IFRD1* and *APiP/EHF* loci likely contain common variants that account for a small fraction of the variation in CF lung function (<2%). The chr20 locus was identified by linkage in affected siblings and region-wide SNP association was noted within the linkage region although a specific gene or mechanism was not implicated. The responsible modifiers in the chr 20 region are likely to be rare (or less frequent) DNA variants as the regional association accounted for only a small fraction of the linkage signal in the CF siblings (492). Further, genome-wide analyses are expected and are likely to confirm novel loci and genes, most of which are unlikely to have been chosen in a candidate gene approach.

**58.3.5.5 Contribution of Environment to the CF Phenotype.** Analysis of lung function measures in twins and siblings when living together and when subsequently living apart demonstrated that genetic factors independent of *CFTR* and environmental factors each accounted for half of the variation in lung function (493). The same appears to be true for nutritional factors (494). Assessing environmental contribution to phenotype is challenging due to the variety of components involved and the lack of objective measurements for many components. Despite these limitations, evidence has been generated linking passive cigarette smoking with reduced pulmonary function (495–497). Interaction between secondhand smoke and variation in the modifier *TGFβ1* causes considerable reduction in lung function measurements (498). Air quality also influences lung function measurements and frequency of pulmonary exacerbations in CF patients (499). Pulmonary colonization with *P. aeruginosa* and *B. cepacia* is an environmentally mediated event that is associated with reduced longevity (78,500,501). The variable effect of both organisms upon pulmonary function indicates that other factors contribute to outcome for the individual patient. These factors are likely to include genetic variability in the bacteria and the host (65,83,502,503). Aggressive nutritional intervention has also been shown to affect outcome (75,504–506). Interestingly, patients vary in their response to nutritional treatment, suggesting that other environmental factors, genetic factors, or both may play a role (507). Socioeconomic status (SES) has a significant influence upon outcome. Not surprisingly, low SES has been associated with poorer growth, higher frequency of pulmonary exacerbations, and reduced survival (508,509).

**58.3.5.6 CFTR Genotypes Associated with Non-CF Phenotypes.** A series of conditions with one or more phenotypic features in common with CF have been shown to be associated with mutations in *CFTR*. In most cases, disease in one organ system (vas deferens, pancreas, sweat gland, sinuses) is similar to that observed in CF patients. Infertility due to CBAVD is an almost invariable feature in males with CF (510). This finding has also been reported in otherwise healthy males and was defined as a separate disorder inherited in an autosomal recessive fashion (511). Screening of these patients for mutations observed in CF patients has revealed that a significant portion carry the ΔF508 mutation (40%) while another 20% are heterozygous for a less common CF mutation and about 10% carry two CF mutations (42,43,512). More extensive mutation analyses of men with CBAVD uncovered a putative disease-associated mutation in both *CFTR* genes in approximately 70% (373).

The distribution of *CFTR* mutations clearly differs between CF and CBAVD patients with partially functional alleles at much higher frequency in CBAVD patients (43,373,513). Furthermore, the 5T splice variant of the intron 8 splice acceptor site is commonly found in men with CBAVD (43). However, the 5T variant is also found in about 10% of individuals in the general population and in fathers of CF patients who also carry ΔF508 on their other chromosome. Thus, 5T is variably penetrant with estimates of penetrance ranging from 0.56 to 0.60 (43,514). The partial penetrance appears to be explained by variability in the length of a polymorphic TG tract immediately adjacent to the 5T variant (515,516). Males with a CF mutation paired with a *CFTR* gene bearing the 5T variant that has 12 or 13 adjacent TG repeats are much more likely to have CBAVD than those with the same *CFTR* genotype but 11 TG repeats (517). Variation in TG repeats affects the efficiency of exon 9 splicing, although the mechanism underlying this process is a matter of debate (518–520).

Males with CBAVD can have normal or elevated sweat chloride values and can display defective chloride conductance in airway epithelia that is qualitatively different from patients with CF (521,522). Although extensive longitudinal data are lacking, it appears that some men with isolated CBAVD and mutations in each *CFTR* gene do not develop chronic, life-limiting pulmonary disease (523). However, detailed study of bronchoalveolar lavage fluid from CBAVD males with two *CFTR* mutations revealed subtle evidence of infection and inflammation (524). Thus, subclinical lung disease may exist in this group of individuals, suggesting that follow-up for signs of progressive lung disease characteristic of CF may be prudent.

Investigation of males with CBAVD has provided important insights into the influence of genotype upon the development of lung disease. This is illustrated by the R117H mutation that permits partial *CFTR* function and

occurs in approximately 10% of CBAVD patients (usually paired with  $\Delta F508$ ) and about 0.3% of CF patients (374,512). How this mutation was able to give rise to phenotypes with and without pulmonary disease was unclear until the genetic context in which the mutation occurs was analyzed. The R117H mutation occurred at least twice but in CFTR genes that have subtle but important differences (357). One of the R117H mutations occurs exclusively in CF patients while the other was seen less frequently in CF patients but exclusively in CBAVD patients. Sequencing of CFTR genes containing each version of R117H revealed that the R117H mutation associated with CF has the inefficient splice variant 5T while CBAVD males carry R117H mutations that have an efficient variant of this splice acceptor site (357). Therefore, the splice variant is predicted to alter the amount of mutant CFTR produced. Higher levels of mutant CFTR bearing R117H appear to cause the CBAVD phenotype while reduced levels produce chronic lung disease characteristic of CF (357). More recent studies have confirmed that the status of the splice variant is correlated with phenotype in patients carrying the R117H mutation (28,373,513). CFTR mutations have been found at higher than expected frequencies in several other conditions with phenotypic similarity to CF. These include idiopathic pancreatitis (525–528), allergic bronchopulmonary aspergillosis (529), asthma (530), disseminated bronchiectasis (531–535), isolated sweat gland dysfunction (427), and chronic rhinosinusitis (536–538).

## 58.4 DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

CF has been recognized as a distinct clinical entity for over 50 years. Initially, multisystem involvement and inheritance pattern differentiated this disorder from other illnesses of infancy and early childhood (2,539). The development of the sweat chloride test in the 1950s provided an objective diagnostic tool. Subsequently, milder forms of the illness associated with diagnostic elevations in sweat chloride concentration were recognized in older children and adults (142). In the late 1960s, the discovery that almost all male patients have congenital reproductive system abnormalities resulted in the diagnosis of older male patients with “borderline” abnormal sweat electrolytes (141,510). In the past decade, the description of patients carrying mutations in each CFTR gene who do not meet clinical criteria for the diagnosis of classic CF further broadened the phenotypic spectrum (44,45). These observations prompted a revision of diagnostic criteria for CF to include advances in our understanding of CF at the molecular level as shown in Table 58-6. The diagnosis of CF requires a characteristic clinical finding and evidence of CFTR dysfunction (540). The advent of nationwide newborn screening for CF prompted adaptation of the diagnostic criteria to account for the lower

sweat chloride concentrations that occur in newborns with CF (541,542).

Each of the clinical features listed on Table 58-7 are suggestive of CF and should prompt testing of CFTR function, especially neonatal MI, steatorrhea, *P. aeruginosa* respiratory tract infection, or the coexistence of multiple features in one patient (37). Many other illnesses can have one or more of these features. Therefore, the diagnosis of CF relies upon accurate testing of CFTR function. Determination of sweat chloride concentrations has been and continues to be the “gold standard” for evaluating CFTR function. Delineation of a panel of common disease-causing mutations in CFTR and the development of assays of CFTR function in respiratory epithelia (nasal potential difference or NPD) provide additional objective methods for diagnosis. DNA and NPD testing can

**TABLE 58-6 Criteria for the Diagnosis of CF**

One or more characteristic phenotypic features (see Table 62-7)
or a history of CF in a sibling
or a positive newborn screening test result
And an increased sweat chloride concentration by pilocarpine iontophoresis or two or more occasions
or identification of two CF mutations
or demonstration of abnormal nasal epithelial ion transport

Data from Rosenstein and Cutting (540).

**TABLE 58-7 Phenotypic Features Consistent with a Diagnosis of CF**

1. Chronic sinopulmonary disease manifested by
a. Persistent colonization/infection with typical CF pathogens including <i>Staphylococcus aureus</i> , nontypeable <i>Haemophilus influenzae</i> , mucoid and nonmucoid <i>Pseudomonas aeruginosa</i> , and <i>Burkholderia cepacia</i>
b. Chronic cough and sputum production
c. Persistent chest radiograph abnormalities (e.g., bronchiectasis, atelectasis, infiltrates, hyperinflation)
d. Airway obstruction manifested by wheezing and air trapping
e. Nasal polyps; radiographic or computed tomographic abnormalities of the paranasal sinuses
f. Digital clubbing
2. Gastrointestinal and nutritional abnormalities including
a. Intestinal: meconium ileus, distal intestinal obstruction syndrome, rectal prolapse
b. Pancreatic: pancreatic insufficiency, recurrent pancreatitis
c. Hepatic: chronic hepatic disease manifested by clinical or histologic evidence of focal biliary cirrhosis or multilobular cirrhosis
d. Nutritional: failure to thrive (protein-calorie malnutrition), hypoproteinemia and edema, complications secondary to fat-soluble vitamin deficiency
3. Salt loss syndromes: acute salt depletion, chronic metabolic alkalosis
4. Male urogenital abnormalities resulting in obstructive azoospermia (CBAVD)

be especially useful in patients presenting with non-classic forms of CF (see below).

The standard method for sweat test is quantitative pilocarpine iontophoresis, in which sweat is collected, weighed, and then subjected to electrolyte determination (543). Specific guidelines for the proper performance and interpretation of this test have been published (135). Collection of adequate volumes of sweat (at least 75 mg, preferably 100 mg or more) is critical to test reliability and accuracy (135). Elevated sweat chloride concentrations have been reported in patients with endocrine, metabolic, and other conditions that are clinically distinct from CF (135). The situation is more complicated for the small fraction of patients (1–2%) who have suggestive clinical features, but sweat chloride concentrations that persist in the borderline or normal range (144,148,151,544). Additional testing in these cases is required to establish the diagnosis. Demonstration of azoospermia in males (510), pansinusitis by CT scan (545), or abnormal pancreatic function by fecal fat determination or elevated serum trypsinogen levels can be helpful (101). Measurement of  $\beta$ -adrenergic stimulated sweat rate may become another diagnostic tool for CF diagnosis (546). This test can distinguish between normals and heterozygotes, and therefore could be particularly useful for the evaluation of symptomatic patients with normal sweat chloride concentrations (136,547,548).

Assessment of ion conductivity in epithelia tissue by measuring NPDs provides an in vivo assessment of CFTR function (296,329,549,550). This procedure is technically challenging and prone to variability depending upon the anatomic site of measurement, test protocol, and equipment used (296,551). However, in centers with extensive experience, CF patients can be reliably distinguished on the basis of higher mean basal potential differences (PD) and minimal change in PD in response to perfusion with a chloride-free solution in the presence of isoproterenol ( $\beta$  agonist) and amiloride (sodium channel blocker) (552). Furthermore, NPD measurement may be a more sensitive assay of CFTR function than determination of sweat chloride concentration. Thus, NPD testing can help establish a CF diagnosis in some patients with borderline abnormal sweat tests and clinical features of CF (553–555).

According to the currently accepted criteria, the identification of deleterious mutations in each CFTR gene of a patient with suggestive clinical features can confirm the diagnosis of CF, even in the absence of an abnormal sweat test (540). An important caveat to the criteria listed in Table 58-6 is how a CF mutation is defined. Many rare mutations have been reported to the CF Mutation Database. The consequences of many of these mutations are unknown. Thus, DNA diagnosis of CF should be based upon mutations shown to alter CFTR function, mutations predicted with a high degree of confidence to have a deleterious effect (e.g., nonsense and frame-shift), or mutations that have been reported in numerous

patients such as those listed in Table 58-3. Preferably, a CF mutation would meet several of these conditions. As noted above, the CFTR2 project has addressed the disease-liability of approximately 160 mutations that each occur at a frequency of 0.01% or greater in approximately 40,000 CF patients. Testing for these mutations identifies 97% of CF-causing alleles which is a considerable improvement over the sensitivity of the current panel of mutations approved by the American College of Medical Genetics (75–87% sensitivity; see below).

An important consideration is the accuracy of the genetic testing. A survey of laboratories offering CF mutation analysis in Europe revealed that only 48% made no mistakes on a standard panel (556). Laboratories that processed more samples made considerably fewer errors. To obtain the highest level of accuracy it is recommended that testing be performed only in certified laboratories that participate in proficiency testing (557–559). A number of academic and commercial DNA diagnosis laboratories in North America and Europe offer testing for the F508del mutation and 5–100 other less frequent CF alleles (560,561). The sensitivity of the test depends upon the population being tested. For heterogeneous European-derived Caucasian populations like those in North America, detection ranges from 75% to 87% of CF alleles (Table 58-3). DNA testing is of greater utility in populations where a limited number of mutations account for 90% or more of CF alleles (Table 58-4). In non-Caucasian races such as native Africans, the test has very low sensitivity. Detection rates approach 75% in African-Americans presumably due to admixture with Caucasians in the United States (376). Ethnicity also contributes to the distribution of CFTR mutations. Individuals self-identified as Hispanic from the southwest United States carry a subset of mutations that are rarely seen in other groups, which may be the result of genetic drift or founder effect (562). Customization of CF mutation panels for mutations observed in Hispanic CF individuals increases sensitivity to levels similar to those obtained in Caucasian CF patients using the ACMG mutation panel (563).

Buccal mucosal cells, peripheral blood samples, or dried blood samples on Guthrie cards can be sent to distant laboratories for DNA testing (564,565). Therefore, DNA diagnosis might substitute for the sweat test in situations where sweat testing is unavailable or unreliable. DNA analysis can also be useful when sweat chloride test results are ambiguous. For example, the mutation 3849 + 10kbC  $\rightarrow$  T has been associated with normal to borderline sweat chloride levels but pulmonary and/or GI manifestations characteristic of CF (45,455,566,567). Testing for CF mutations can assist with diagnosis since the 3849 + 10kbC  $\rightarrow$  T mutation is included in panels used by many diagnostic labs. DNA testing of fetuses with an echogenic bowel can be useful. There is an association between this finding and CF, but the precise risk that a fetus with echogenic bowel will be affected

with CF is not known (568,569). Estimates of risk range from 1.3% to 13.3% (570). Since an accurate prior probability is unavailable, Bayesian analysis for fetuses found to have one CF mutation is unreliable. However, if two CF mutations are discovered in the fetus, or both parents are shown to be carriers, then clinical management can be adjusted accordingly. Furthermore, the nature of the mutation in *CFTR* may influence the risk for fetal echogenic bowel. Deletions of *CFTR* have been found in a higher than expected fraction of CF-fetuses with echogenic bowel, loop dilation, or gall bladder anomalies (571).

### 58.4.1 Prenatal Diagnosis

Highly accurate DNA-based prenatal diagnosis is available for families with a previously affected child and for couples where both members are known carriers of a CF mutation (572–574). Healthy siblings can also be tested to determine carrier status. However, about 25% of Caucasian families will carry a rare mutation not included on CF mutation panels. Although a variety of techniques have been devised to screen an entire gene for mutations, none is currently practical for routine diagnostic testing (574,575). Linkage analysis with polymorphic markers can be used in families where one or neither mutation can be identified (573,576,577). Use of polymorphic microsatellite markers flanking and within the *CFTR* gene virtually eliminates mistyping due to recombination, providing an accuracy of 99% or greater for prenatal and carrier diagnosis (382,578–580). More recently, preimplantation genetic diagnosis for CF has been successfully performed upon single cells derived from in vitro fertilized embryos (581). This technique provides an alternative to some couples who would not undergo fetal testing.

### 58.4.2 Diagnosis by Newborn Screening

The issue of screening newborns for CF has been controversial. Central to this proposal is whether early diagnosis alters outcome for patients and, if so, does the degree of improvement outweigh the costs. These points were moot until the development of an inexpensive and reliable test with acceptable levels of specificity and sensitivity. In the early 1980s, the immunoreactive trypsinogen test (IRT) was shown to be a promising method for CF neonatal screening (16,582). The sensitivity and specificity of this test depends upon the concentration that is used to determine an abnormal result. In a study of 220,865 newborns from Wisconsin, the test had a sensitivity of 87% using a high “cutoff” value of 180 ng/ml (583). Sweat testing confirmed the diagnosis in 12.5% of neonates with elevated IRT concentrations in that study. Use of a lower “cutoff” value (140 ng/ml) followed by a second IRT test resulted in a sensitivity of 95.2% and positive predictive value of 32% (17).

In 1983, an Ad Hoc Committee Task Force on newborn screening sponsored by the U.S. CF Foundation raised several important concerns and recommended that screening not be implemented (584). In addition to acknowledging that the benefits of early intervention were unclear, the committee questioned the possible effects of screening upon parent–child bonding and reproductive decision making, and the reliability of the IRT. Pilot screening studies performed in Europe, Australia, and the United States have addressed most of the concerns of the Task Force (17,23,585,586). Furthermore, coupling of IRT with DNA testing considerably improves the positive predictive value of newborn screening (18,22,583,587). Two tier (IRT and DNA) screening also reduces false positives, and eliminates the need for second IRT measurements (21,75). Unwanted carrier detection does occur as a consequence of the two tier test (21). However, it appears that a substantial fraction of infants with a positive IRT who carry one CF mutation have a mild form of CF (588–590).

Neonatal screening for CF is now widespread in North America, Europe, and Australasia as optimization of molecular-based therapies may require early intervention. For example, patients identified by newborn screening in Colorado demonstrated airway inflammation before symptoms of lung disease evolved (58). These data suggest that therapy directed at the basic defect may have to be initiated in infancy. Neonatal screening may be the only reliable method to identify patients before considerable morbidity is present. Furthermore, evidence is accumulating that CF patients identified by newborn screening have better outcomes than those diagnosed by traditional methods. Improvements in nutrition (20,591,592) and lung function (592,593) have been observed as benefits of earlier diagnosis. These benefits have translated into fewer complications, reduced need for therapy and improved survival (594–596). Thus, the risk to benefit ratio may be tipping in favor of implementing newborn screening for most populations (597).

### 58.4.3 Screening for CF Carriers in the General Population

The discovery that one mutation is common in CF raised the possibility of population screening for CF carriers. Opinions vary considerably regarding the feasibility of large-scale screening programs (598–603). Comprehensive reviews on this topic are available (604–607). Since it is not possible to detect all mutations easily and inexpensively, concern has arisen regarding the use of a test that cannot detect all carriers (608). A negative test at an 85% level of mutation detection reduces the chance that a Caucasian individual is a CF carrier from about 1 in 30 to 1 in 170. This may appear to be a valuable reduction in risk. However, in a population-based screening program, a large number of couples will be identified

with one member being a CF carrier. For the majority of couples, the other member will have a negative test. Since a negative test does not eliminate the chance that an individual is a carrier, many couples will be given an increased risk of having an affected child (about twice the population risk) without the possibility of further testing.

In the United States, a consensus report was issued by an NIH Advisory Council recommending that screening not take place until 95% of CF mutations can be detected (609). Similar recommendations for CF carrier screening have been issued by the American Society of Human Genetics and World Health Organization (606,608). At a 95% level of mutation detection, couples in which one partner is a CF carrier and the other has a negative mutation test will have the same risk as if they did not have any testing. Studies have been performed to assess the impact of carrier screening upon the general population with inconclusive results (586,610–613). Small-scale population studies (<5000 individuals) involving pregnant patients enrolled in HMOs or attending an academic medical center clinic indicated that screening for CF was desired and the necessary pre- and post-test phases could be accomplished (28,614). In 1997, a 14-member organization by the NIH in the United States concluded that testing for CF mutations should be offered to couples seeking prenatal care even though mutation detection rates in the general population had not exceeded 90% and large-scale screening projects utilizing a wide variety of clinical settings had not been performed. Guidelines for the implementation of CF mutation testing in the general population have been issues considered by the American College of Medical Genetics (615). A pan-ethnic panel consisting of mutations that exceed 0.1% frequency in the general population was recommended and has been amended based upon screening results (616,617). Important issues remain regarding the utility of screening in non-Caucasian couples and implementation in clinical practices (618,619). There have been reports that implementation of population-based carrier screening has resulted in a decrease in the incidence of CF (620,621).

#### 58.4.4 Differentiating Between CF and Congenital Bilateral Absence of the Vas Deferens

Obstructive azoospermia due to absence (or malformation) of the vas deferens, an almost invariable feature in males with CF, has been reported as a separate autosomal recessive disorder (141,146,511,622). The first clinical report of CBAVD appears to be that of Michelson in 1949 (623). The disorder is rare in healthy men (0.04%) but is the cause of infertility in about 2% men with obstructive azoospermia (624). The finding of chronic sinus and respiratory disease in some men with CBAVD lead to the suggestion that it may be a variant of CF (510,625). This perception has been strengthened

by the detection of CF mutations in a large fraction of men with CBAVD (see above). Presence of persistent pulmonary or pancreatic disease in males with CBAVD and elevated sweat chloride concentrations would indicate a CF diagnosis (Table 58-5). DNA and NDP testing can be useful in less obvious cases. A diagnosis of CF should be entertained in men with CBAVD carrying two *CFTR* mutations (Table 58-3) and/or having chloride conductance abnormalities in nasal epithelia similar to that observed in CF patients (626). Identification of mutations in *CFTR* primarily associated with isolated CBAVD (42,43,373,513) or NPD measurements that are not consistent with CF (521) or normal (626) would suggest retention of the CBAVD diagnosis. Considering the implications of a diagnosis of CF, labeling these otherwise healthy males as a variant of CF is not appropriate. Furthermore, evidence of genetic heterogeneity indicates that *CFTR* may not be abnormal in all men with this condition (46). Finally, some men with CBAVD have lung disease and some do not, so the long-term prognosis of this group is unknown (523,524,627). Until further data becomes available, monitoring of men with CBAVD for clinical signs of lung or pancreatic disease characteristic of CF appears prudent.

#### 58.4.5 Non-Classic CF in the Absence of *CFTR* Mutations

As noted previously, patients with abnormal *CFTR* function may present with disease in a subset of organ systems affected in classic CF. These patients can present as diagnostic dilemmas since the reduction in *CFTR* function may be moderate, thereby creating subtle phenotypes with borderline abnormalities in the sweat test or NPD. Etiologic heterogeneity can further complicate diagnosis of patients presenting with non-classic CF (7,8). Some patients with non-classic presentations have been found with mutations in the *SBDS* gene responsible for Shwachman–Diamond syndrome or in the  $\beta$  subunit of the ENaC (628,629). More recently, patients presenting with hyponatremic dehydration and elevated sweat chloride concentration have been found with a mutation in *carbonic anhydrase 12*. The same mutation (G143K) occurred in homozygosity in two different consanguineous Bedouin pedigrees (630,631). These patients did not manifest other features of CF. Although these cases of genetic heterogeneity for CF traits such as elevated sweat chloride concentration are likely to be rare, distinguishing their disease from CF is important for the new insight into organ system disease in CF, accurate prognosis, and appropriate therapy.

### 58.5 MANAGEMENT

Therapy of CF has the following aims: preservation of lung function, optimization of nutritional status, minimization of complications, and maintenance of psychosocial

well-being. Achievement of these goals requires a multifaceted management plan delivered by a team of health care professionals. For this reason, many CF patients receive care at specialized “CF Centers.” Implementation of multidisciplinary care and improvement in traditional forms of therapy have led to progressive increases in survival with most patients now living well into their third decade (38).

### 58.5.1 Pulmonary Therapy

Lung disease is the life-limiting factor for most CF patients. For this reason, a great deal of effort is expended to retard progression of pulmonary damage. At the present time, therapy is targeted at mucus clearance and control of infection (Table 58-8). Coughing is a potent method to expel mucus from the airways and is the predominant large airway clearance mechanism for CF patients (632). Chest percussion and/or postural drainage may assist this process in the small airways for some patients (633-635). Exercise has been advocated on the basis of patient well-being but may also promote more efficient sputum expectoration (636,637). A significant fraction of patients have a reactive airway component to their disease that can be improved by  $\beta$ -adrenergic bronchodilators (638). Control of bacterial infection, especially *P. aeruginosa*, is the mainstay of pulmonary treatment (56). Reduction of the inflammatory response using steroids appeared promising but this benefit may

be outweighed by significant complications (639,640). Improved methods of mucus removal can aid in the clearance of secretions from the airways. Mucus secretions from CF airways contain large amounts of DNA that significantly increases its viscosity. Cloning of human DNase I provided a means to digest DNA in mucus (641). Clinical trials demonstrated improvement in lung function and a reduction in the frequency of respiratory tract exacerbations in patients receiving aerosolized rhDNase I (Pulmozyme) (642-644). Actin is also abundant in secretions from CF patients. Low-dose long-term macrolide antibiotics are efficacious in the treatment of diffuse panbronchiolitis, a chronic lung disease with several features in common with CF. On this basis, macrolide treatment has been tried in CF patients with positive results (645-647). However, the mechanism by which macrolides improve outcome for CF patients is unclear (648). Lung transplantation is the last resort in selected patients with extensive irreversible damage (649).

### 58.5.2 Novel Therapies for CF Lung Disease

An increased understanding of the etiology and pathogenesis of CF at the molecular level has opened a whole new array of therapeutic possibilities (650,651). These range from provision of normal CFTR to airway cells to modulators of the immune system (Table 58-8). Of all the treatment regimens being considered for CF, gene

**TABLE 58-8 Treatment of CF Lung Disease**

Pathology	Treatment Goal	Current Options	Future Possibilities
Defective CFTR gene	Replace with normal gene	None	Gene therapy
	Translation of RNA transcripts containing nonsense mutations	None	Premature termination suppressors
Abnormal protein	Replace with normal protein	None	Protein replacement
	Enhance mutant protein folding	None	Chemical chaperones, bisaminomethylbithiazoles
	Augment mutant protein function	None	Potentiators of channel gating, phosphodiesterase inhibitors, protein phosphatases
Altered ion transport	Utilize alternative pathway of chloride secretion	None	ATP/UTP
	Block sodium hyperabsorption	None	Amiloride
Abnormal airway mucus	Reduce viscosity	Pulmozyme Hypertonic saline	Gelsolin
Obstruction	Facilitate clearance	Airway clearance techniques	?
Airway reactivity	Reduce reactivity	$\beta_2$ -agonists Cromolyn Aerosolized steroids	?
Infection	Control bacterial and viral replication	Antibiotics Influenza vaccine	<i>Pseudomonas</i> vaccines Immunoglobulin therapy Antimicrobial peptides
Inflammation	Decrease immune response	Corticosteroids <sup>a</sup> Ibuprofen	Protease inhibitors Anti-oxidants
Irreversible airway destruction	Replace damaged tissue	Lung transplantation	?

<sup>a</sup>Limited to cases complicated by bronchiolitis, ABPA, or severe airway reactivity.

therapy has received the greatest attention, although small chemical correctors and potentiators are showing considerable promise.

Providing affected epithelial tissues, especially those in the lungs, with a long-lasting source of normally functioning CFTR is an attractive and desirable goal. Consequently, a considerable amount of effort has been directed toward this goal and, although efficacy has remained elusive, the problems limiting successful gene replacement have been defined (652,653). Recombinant adenovirus is an efficient vector for transient expression that can be produced in titers sufficiently high enough for human trials. Expression of CFTR transcripts and protein from this vector has been detected for as long as 6 weeks in tracheal cells from cotton rats and rhesus monkeys (654,655). However, adenovirus vectors produce an inflammatory response in animals and have caused adverse events in human subjects (656–660). Since efficacy has not been demonstrated and safety concerns remain, adenovirus trials are no longer being conducted for CF. Adeno-associated virus (AAV) is a non-pathogenic parvovirus that can integrate into the genome of the host. Correction of the chloride conduction deficiency in CF cells and RNA expression for up to 6 months has been achieved using AAV-CFTR vectors (661,662). AAV vectors appear to have low toxicity and can be administered repeatedly although efficacy for CF has not yet been convincingly demonstrated (663–665). Furthermore, recombinant AAV vectors are difficult to produce in high titers and their ability to integrate appears to be altered from wild-type AAV (666,667). Other vectors that have been considered include sendai virus and feline immunodeficiency virus (668,669). Delivery of naked plasmid DNA mixed with cationic liposomes has shown some promise in animal models (670,671), although results have been mixed in human trials (672). Synthetic vectors that utilize a receptor-mediated endocytosis pathway for DNA delivery may be more efficient and might avoid some of the problems of biologic vectors (673).

The difficult issues presented by gene therapy have lead to renewed efforts to target the molecular defect (674,675). The discovery that CFTR containing the common mutation,  $\Delta F508$ , is partially functional suggested that the majority of CF patients might be treated by increasing the amount of mutant CFTR at the cell surface (254,412,676). Altering the fate of misfolded mutant CFTR is an interesting but difficult task. It may require manipulation of the normal process of intracellular trafficking which could have detrimental side effects. Several strategies have been suggested: use of chaperones, alteration of trafficking regulated by G-proteins, and increased CFTR expression (676–681). A second phase of this theoretical treatment would involve maximization of mutant CFTR function. Application of high levels of the phosphodiesterase inhibitor IBMX appears to stimulate the chloride currents exhibited by mutant CFTR expressed in *Xenopus* oocytes (255). However,

IBMX did not affect chloride secretion in nasal epithelial cells of CF patients (682). Mixed results have been obtained with Milronone, another phosphodiesterase inhibitor (683,684). The protein phosphatase genistein shows promise as a direct activator of wild-type and mutant forms of CFTR (685,686). High throughput small molecule screens have identified new candidates for CFTR activation and gating (419). One compound termed VX-770 that augments the function of CFTR bearing the gating mutation G551D has shown dramatic effect in human trials (420). Pronounced reduction in sweat chloride concentration and improvement in lung function (FEV1%pred) were maintained over a 4-week period. The success of this approach will probably drive a search for other compounds that augment CFTR bearing mutations that affect other functional properties. Indeed, several compounds show promise for correcting the folding defect of CFTR with the F508del mutation (687,688).

Therapies selective for other CFTR genotypes have been developed. Clinical trials are underway based on the observation in vitro that high doses of aminoglycoside antibiotics cause read through of premature termination codons (689,690). Administration of aminoglycoside-derived compounds to nasal epithelia corrects the ion transport defect in patients carrying a nonsense mutation (691). Although this approach appears promising, only a small fraction of CF patients carry mutations that would respond to this therapy.

Epithelial cells contain chloride channels that are distinct from the channel encoded by CFTR (284,692,693). These channels can be activated by different mechanisms than those employed by CFTR. It may, therefore, be possible to exploit other pathways of epithelial chloride secretion and compensate for electrolyte abnormalities caused by mutations in CFTR (694). The observation that ATP and UTP applied to airway epithelial cells elicit chloride secretion in normal and CF patients demonstrates the clinical feasibility of this approach (340,695). Alternatively, it may be possible to improve the hydration of epithelial secretions by affecting the movement of ions other than chloride (340). For example, blockage of sodium absorption in airway epithelia of CF patients by aerosolized amiloride resulted in reduced sputum viscosity and elasticity and subtle signs of improved pulmonary status (696,697). Alternatively, rehydration of ASL by administration of aerosolized hypertonic saline appears to improve mucus clearance and reduce inflammation (698–700).

Novel approaches have also been devised to control viral and bacterial infection and the inflammatory response they elicit. Vaccination of CF patients against *P. aeruginosa* has been attempted using a variety of antigens derived from the bacteria (701,702). Although well-tolerated and eliciting significant rises in titers of anti-*P. aeruginosa* antibody, clinical status has not been affected by immunization (701). Administration

of immunoglobulin enriched for anti-*P. aeruginosa* antibodies is an alternative approach to the control of chronic *Pseudomonas* lung infection (703). An increased understanding of the molecular adaptations of *Pseudomonas* that permit colonization of CF patients should identify new therapeutic targets (502,704–706). Bacterial genes that regulate formation of biofilms are particularly attractive (707,708). By the same token, greater insight into role of CFTR dysfunction in the pathogenesis of CF lung disease has suggested novel treatments such as antimicrobial peptides and agents that alter electrolyte concentration in ASL (347,348,709–711).

Inflammation and subsequent tissue destruction is a major component of CF lung damage (712). It appears that long-term alternate-day with anti-inflammatory steroids such as prednisone may improve lung function but treatment side effects remain problematic for this medication (713,714). Non-steroidal anti-inflammatory agents appear more promising. Ibuprofen given over a 4-year period reduced the rate of pulmonary function decline with few adverse reactions (714). Other clinical strategies to control inflammation include modulators of the NFκB pathway, anti-oxidants, and anti-proteases (715–717). Aerosol delivery of α1-antitrypsin or secretory leukoprotease inhibitor may be useful to counteract neutrophil elastase in epithelial airway secretions (718–720).

### 58.5.3 Nutritional and Other Therapies

Normal growth and development in children and maintenance of nutritional status in adults are important goals in the management of CF patients. These are achieved by providing exogenous pancreatic enzymes, supplementing fat-soluble vitamins (A, D, E, and K) and providing sufficient calories to compensate for less efficient absorption and increased energy requirements. Enzyme replacement remains central to the treatment of malabsorption. Pancreatic extract has been used for CF since the 1930s (51). Dosage is empirically based; sufficient amounts are taken at each meal-time to control steatorrhea and allow appropriate weight gain (51). Considerable patient-to-patient variation exists in enzyme requirements. Normal fat absorption, even at very high enzyme doses, is rarely achieved (721,722). Efficacy of pancreatic enzyme replacement can be limited by gastric acid inactivation; therefore, current preparations of pancreatic enzymes have an enteric coating that dissolves at pH levels that exist in the small intestine. Reduction of gastric activity with H<sub>2</sub>-blockers, sodium bicarbonate, and prostaglandin analog can improve enzyme effectiveness in some patients (723–725). Although relatively safe, some patients taking high-dose pancreatic supplements have had colonic strictures (726,727).

Dietary manipulation to reduce fat intake had been in vogue in the past, but a normal diet with moderate amounts of fat is currently recommended (51). Reduction

in fat intake may be contraindicated since CF patients have deficiencies in essential fatty acids that cannot be attributed to malnutrition (728). Impaired uptake and/or metabolism of fatty acids appears to be associated with CFTR dysfunction, although the precise mechanism is unknown (729–731). Correlation between the degree of fatty acid deficiency and severity of lung disease has been documented (732,733). Correlation between *CFTR* genotype, pancreatic status, and level of the fatty acid docosahexaenoic acid (derived from n-3 synthetic pathway) has been reported, but correlation with levels of the fatty acid arachidonic acid (derived from n-6 pathway) has been inconsistent (734,735). More recent studies of CF mice have also questioned the connection between essential fatty acid deficiency and CFTR dysfunction (736). The lipid imbalance in CF mice can be corrected by oral administration of lipid emulsions (730). These observations have prompted clinical trials to evaluate the potential therapeutic efficacy of correcting lipid imbalances in CF patients. Calorie supplementation of the diet is advocated for many CF patients due to increased energy consumption for respiration and infection control. The most important factor may be attention to the dietary preferences of the patient to ensure that adequate calories are consumed (737). For some patients, enteral supplementation is being used to provide adequate caloric intake (506).

Liver disease is the second most common cause of death for CF patients (40). As outlined for lung disease, treatment is aimed at several phases of pathogenesis. The goals are prevention of mucus plugging of bile ducts and reduction of hepatotoxicity caused by bile acids. Choleric agents can be used to reduce bile viscosity and prevent mucus plugging. Bile acid therapy is the predominant treatment for chronic cholestasis (738). Ursodeoxycholic acid is used to alter biliary bile and composition to minimize cell damage. Portal hypertension can be treated by sclerosis of varices. For patients with advanced disease, liver transplantation is the only therapeutic option.

### 58.5.4 Animal Models for CF and Their Role in Therapy Development

Generation of mice with defective *CFTR* genes (CF mice) have led to advances in both the understanding of CF pathogenesis and treatment (739). A number of CF mice lines have been created by “knockout” techniques (740,741). Although epithelial chloride transport is abnormal in the lungs and GI tract of these animals, the clinical phenotype differs from their human counterparts (740–742). Intestinal obstruction and perforation are a frequent life-limiting complication in the mice but significant lung disease is not readily apparent (740). However, the lungs of CF mice are not normal. CF mice appear to have more difficulty than their normal littermates in clearing pulmonary infections after

repeated exposure to bacteria that colonize human patients (*S. aureus* and *B. cepacia*) (743–745). Furthermore, CF mice are significantly more susceptible to chronic infection with *P. aeruginosa* that express alginate, a polysaccharide found on the surface of *Pseudomonas* that colonize CF patients (746,747). Finally, it appears that pathology in the lungs, liver, and pancreas of CF mice that mimics those seen in CF patients develops over time, and may be substantially influenced by differences in genetic background (i.e., strain differences) (485,748). These strain differences may be a consequence of variation in alternative pathways of chloride transport, which are more active in mice than in humans (749). Analysis of different CF mice strains suggests that the magnitude of conductance via the alternative pathways is genetically determined (750). Furthermore, studies of inbred mouse strains reveal differences in susceptibility to colonization with *Pseudomonas* (751). By combining these observations, it may be possible to create a murine model of CF lung disease that closely approximates the human situation.

Mice bearing CF mutations observed in humans such as  $\Delta F508$  and G551D have also been generated (752–754). Similar to their human counterparts,  $\Delta F508$  mice manifest intracellular processing defects of CFTR that are relieved by temperature reduction. The G551D CF mice had reduced rates of fatal intestinal blockage, a phenotype reminiscent of the lower frequency of MI in CF patients with the G551D mutation (435,754). Even if CF mice do not have a phenotype that precisely matches with those observed in humans, imitation of the biochemical phenotype of CF at the cellular level will be invaluable for the design and preliminary testing of the various therapies currently under consideration (683,684,755). Careful study of phenotype variation in CF mice will facilitate the identification of genetic modifiers of disease severity (484–487). Murine models can also be used to test the contribution of genetic modifiers to disease variation. For example, dysregulation of the ENaC in the absence of CFTR leads to hyperabsorption of sodium in the lungs of CF patients (see above). Transgenic mice that overexpress the  $\beta$  subunit of ENaC (but not  $\alpha$  or  $\gamma$ ) in their lungs develop pulmonary disease that closely resembles the pathology observed in CF patients even though functional CFTR is present (756). Intriguingly, two patients with CF-like lung disease in the absence of CFTR mutations had mutations in the  $\beta$  subunit of ENaC (629). Modifiers such as the  $\beta$  subunit of ENaC could provide targets that are more amenable to manipulation than CFTR.

Two new animal models of CF hold considerable promise for advancing our understanding of CF pathophysiology, especially for early stage disease. A large mammal model for CF has been developed using the pig. The porcine model for CF shares a number of features with CF in humans including neonatal intestinal obstruction, pancreatic endocrine and exocrine

dysfunction, hepatocellular disease (757), and polymicrobial lung infection (758). Of note, the CF pig develops intestinal obstruction that is morphologically and temporally similar to MI in CF neonates except that nearly 100% of CF piglets are affected. A high rate of intestinal obstruction (~75%) is also observed in a ferret model of CF (759) suggesting that the lower rate of this complication in humans with CF may be due to the presence of modifying factors. Treating obstruction in the pig and ferret model is challenging and currently limiting full utilization of these models. Once intestinal obstruction has been addressed, these animals will aid the search and evaluation of therapies for CF as they have pulmonary systems that are quite similar to humans.

### Biography

**Dr. Garry Cutting** is Professor of Pediatrics and Medicine and the Aetna/U.S. Healthcare Professor of Medical Genetics at Johns Hopkins University School of Medicine. Dr. Cutting received his undergraduate and medical degree at the University of Connecticut. In 1983, he went to Johns Hopkins University where he completed his residency in pediatrics and a fellowship in medical genetics before joining the faculty in 1989. Dr. Cutting's primary studies have been in the molecular genetics of cystic fibrosis and more recently elucidating the factors underlying variation in the severity of cystic fibrosis. His previous research achievements include the cloning and characterization of a new class of GABA receptor subunits (GABAc) and structure/function studies of voltage gated chloride channels. He also directs the Postdoctoral Clinical Laboratory Training Program in Medical Genetics and he is the Director of the DNA Diagnostic Laboratory at Johns Hopkins University School of Medicine. Dr. Cutting is the co-editor of the journal *Human Mutation* and Board Member of the Federation of American Societies for Experimental Biology. He is the recipient of numerous grants including a MERIT award from the NIH and has published over 150 peer-reviewed articles.

This article is a revision of the previous edition article by Deborah A Meyers, Eugene R Bleecker, volume 2, pp 1395–1406, © 2007, Elsevier Ltd.

### GLOSSARY

**Bronchial hyperresponsiveness** – A condition of lung airways characterized by easily induced and/or exaggerated constriction of airways following some triggering event.

**Candidate gene study** – A hypothesis-driven form of genetic study in which genes suspected in disease pathology are examined for variations between cases and control individuals. Candidate gene studies require a previous understanding of disease biology, as candidate genes are selected largely on the basis of biological plausibility.

**Forced expiratory volume in 1 second (FEV<sub>1</sub>)** – A measure of lung function in which the amount of air a patient can expel in 1 s following a deep inhalation is measured by spirometry.

**Forced vital capacity (FVC)** – A measure of lung function in which the full volume of air a patient can expel following a deep inhalation is measured by spirometry.

**Gene–environment interaction** – Phenotypic effects resulting from effects of the environment on given genotypes. In the context of asthma genetics, this would refer to the influence of environmental factors on both susceptibility to asthma and the severity of disease.

**Gene–gene interaction** – Also called epistasis. Refers to phenotypes that arise only when specific alleles are present at two or more different loci.

**Genome-wide association study (GWAS)** – A hypothesis-free (and often hypothesis-generating) form of genetic study in which hundreds of thousands of single nucleotide polymorphisms are genotyped in large cohorts of cases and controls. The large panel of polymorphisms is analyzed for variations in frequency between cases and controls, allowing for identification of disease susceptibility loci.

**Genome-wide linkage study** – A hypothesis-free (and often hypothesis-generating) form of genetic study in which the genomes of disease-affected and unaffected family members are screened with a panel of genetic markers. Owing to the smaller amount of recombination expected between family members, regions containing susceptibility loci can be identified with a comparatively small number of genetic markers.

**Peak expiratory flow (PEF)** – A measure of lung function in which the speed of a patient's exhalation is measured, through the use of a peak flow meter.

**Pharmacogenetics** – The study of genetic variation that affects the responses of individuals to medication.

### NOMENCLATURE

FEV<sub>1</sub> – Forced expiratory volume in one second

FVC – Forced vital capacity

GWAS – Genome-wide association screen

PEF – Peak expiratory flow

SNP – Single-nucleotide polymorphism

### 59.1 INTRODUCTION

#### 59.1.1 Definition

Asthma is a common, chronic respiratory disorder featuring episodic shortness of breath, often at night and usually accompanied by a nonproductive cough. Wheezing is usually observed on clinical examination during exacerbations, with normal breath sounds when asthma is well controlled. Asthma is characterized by episodic airway obstruction accompanied by airway inflammation and, in some cases, irreversible structural alterations to

airways. There are many different definitions of asthma. The most recent Global Initiative for Asthma's Global Strategy for Asthma Management and Prevention report (updated in 2009) provides the following definition, which integrates symptoms and addresses the underlying cellular mechanisms of asthma:

*Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role. The chronic inflammation is associated with airway hyperresponsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread, but variable, airflow obstruction within the lung that is often reversible either spontaneously or with treatment (1).*

Acute asthma attacks are episodes in which patients experience difficulty breathing, usually as a result of constriction in the airways of the lung. Symptoms of acute attacks can usually be alleviated through the use of inhaled bronchodilators. These medications relax the smooth muscle of the airways, opening the airways and alleviating the increased work of breathing. Over the long term, structural changes can occur in the lungs that impact lung function, with excess mucus production, infiltration of cells of the immune system mediating chronic inflammation, and thickening of the walls of the airway that irreversibly limits air space. Some of these changes, such as immune-mediated inflammation, can be controlled through medication.

Although asthma is usually recognized through the acute episodes of asthma attacks, including wheezing and sometimes irreversible declines in lung function, asthma has an important immune system component as well. Roles for many immune cells and mediators have been described. There is a clear connection between asthma and atopy, although this connection is not absolute. Atopic individuals are more prone to developing asthma, and much of the prevalence of asthma can be linked to specific allergies (2). However, not all atopic individuals develop asthma, and not all asthmatics have detectably elevated allergic responses. Nonetheless, dysregulated immunity appears important in the development of asthma, with elevated serum IgE levels, excess release of allergic mediators from mast cells, infiltration of eosinophils into the lungs and inflammation in the airways, and skewed  $T_H1$  and  $T_H2$  responses frequently observed in asthmatics. Reduction of chronic inflammation in the lungs is part of the strategy for long-term control of asthma, through the use of anti-inflammatory agents like inhaled glucocorticoids.

### 59.1.2 Asthma Diagnosis

Asthma sufferers can present with a variety of symptoms, and the transient nature of the acute attacks (the most obvious symptom) can make actual diagnosis difficult.

Most asthmatics will report recurrent episodes of difficulty breathing, and wheezing will often (although not always) be observed on examination. A series of secondary characteristics can be evaluated to aid in diagnosis. Bronchial hyperresponsiveness (BHR), the tendency of asthmatic airways to overreact to irritants or stimuli, can be measured by either direct or indirect means (3). Direct challenges are the most commonly performed tests, and they specifically target the response of airway smooth muscle. These involve exposure of the airways to a substance, like methacholine, that binds to receptors on smooth muscle cells and promotes muscle contraction, constricting the airways. The reduction in lung function can be assayed, as can the response to treatment with bronchodilators. Most asthmatics will display larger-than-expected reactions in direct challenge tests (4). Indirect challenge tests involve stimuli that will cause activation of the immune cells that are resident in the asthmatic lung. These immune cells will release mediators that act on smooth muscle in the airways causing constriction (5). Common indirect stimuli include exercise, dry or cold air, and adenosine monophosphate. Indirect tests mimic the triggers of most asthma attacks in daily life, and therefore may be more clinically relevant (3). Overreactions to indirect challenges indicate the presence of immune cells like mast cells and eosinophils in the lung, indicative of asthma.

Several measures of lung function are commonly used (1). Peak expiratory flow (PEF) is a measurement of the patient's maximum speed of expiration. It is measured with a peak flow meter; modern meters are inexpensive, portable plastic devices, which enable home measurement and recording of PEF that aids in the monitoring of early deterioration and response to therapy. Forced expiratory volume in 1 s ( $FEV_1$ ) is the amount of air exhaled in 1 s following a deep inhalation, while forced vital capacity (FVC) is the maximal amount of air that can be expelled following a full inhalation. Both  $FEV_1$  and FVC are measured by spirometry. The reversibility of  $FEV_1$  by treatment indicates a diagnosis of asthma (6).

As mentioned previously, there is a clear but imperfect connection between asthma and allergy. As such, it is often useful to determine a patient's allergy status, either through skin tests or measurement of allergen-specific or total IgE levels in serum. Allergies and allergic disease (especially allergic rhinitis) increase the probability of an asthma diagnosis. In addition, identifying allergens to which a patient reacts can aid in identifying environmental exposures that trigger asthma attacks.

In the description of studies of the genetics of asthma that follows, many different phenotypes are considered end points for studies. Some studies consider actual asthma diagnoses, but others rely on different criteria. Measurements of lung function, allergic reactions, levels of serum IgE, and eosinophilia are cited as end points. In this chapter, these other criteria that serve somewhat as surrogates for asthma will be described as "asthma-related phenotypes."

### 59.1.3 Asthma Prevalence and Severity

Owing to the variability of the disease and a lack of generally agreed upon standards for diagnosis, it is difficult to estimate the prevalence of asthma, and variations in practice from country to country complicate worldwide estimates. In the United States, it is estimated that at least 22.9 million Americans suffer from asthma. Asthma is the leading chronic illness in US children, with 6.8 million affected in 2006 (2). Global rates of asthma range from 1 to 18% of the population from different countries (1). Prevalence is rising in locations where rates were previously low, and variation in rates from country to country appears to be diminishing (7).

Asthma was previously categorized based on the severity of symptoms in untreated individuals. Four groups were recognized: intermittent, mild persistent, moderate persistent, and severe persistent (8). However, these classifications did not account for the difficulty of controlling symptoms with treatment. Mild persistent asthma in one individual might be resistant to treatment while severe persistent asthma in another person might respond well and be thoroughly controlled with proper medication. Current consensus is to classify asthma on the basis of both severity of symptoms and the level of control of those symptoms (8,9). Mild asthma is therefore well controlled with low-intensity treatment, while severe asthma requires high-intensity treatment for full, and sometimes only partial, control. The advent of new treatments, allowing better control in certain situations, will hopefully allow currently severe forms of asthma to be reclassified as mild asthma in the future. Further characterization of severe asthma continues, with lower lung function, more frequent sinopulmonary infections, more persistent symptoms and higher health care requirements in severe asthmatics (10). Additional work has shown the existence of multiple distinct groups among severe asthma sufferers; differences between groups are apparent in age, age of onset of disease, presence of atopy, requirements for medication and health care, and impairment and reversibility of lung function (11). Appreciation of these groups will likely aid in care, as the underlying causes and therefore the most appropriate treatments for each type of severe asthma are likely to be different.

## 59.2 THE GENETICS OF ASTHMA AND ALLERGIC DISEASES

Twin studies have shown that there is a genetic element to asthma susceptibility, with heritability of the condition estimated at between 0.36 and 0.77 (12–15). The first study to link a genetic locus (chromosome 11q13) to asthma was published in 1989 (16). Since then, more than 600 candidate genes described in more than 1000 publications have been found in connection to asthma or an associated phenotype, like elevated IgE levels, BHR, or eosinophilia.

### 59.2.1 An Overview of the Analysis of the Genetic Contributions in Asthma

Researchers have been successful in identifying the genetic underpinning of over 3000 single-gene disorders. However, it has been comparatively difficult to identify the genetic basis of complex genetic disorders, such as asthma, allergic disorders, and autoimmune diseases, with multifactorial inheritance and significant environmental contributors. Three study designs are routinely employed to investigate genetic contributions in complex diseases: candidate gene association studies, genome-wide linkage studies and genome-wide association studies.

**59.2.1.1 Candidate Gene Studies.** In a candidate gene association study, a particular gene (or set of genes) is selected for study based on its biological plausibility or suspected role in the phenotype of interest. The incidence of variants in this gene is compared between a group of individuals affected with the phenotype (cases) and a group of controls. The strength of such a design lies in the statistical power and relative ease of recruiting large cohorts, compared to family-based studies. The main limitations of such a design are its inability to identify novel or unsuspected genes and pathways contributing to the pathogenesis of a disorder, and its susceptibility to unknown population structures in cases or controls. Candidate gene association studies are best suited to identifying common genetic variants of modest effect (17).

More than 1000 papers have been published with candidate gene studies examining asthma and related phenotypes, identifying more than 600 candidate genes. However, surprisingly few of these candidate gene discoveries have been rigorously replicated, and many have been examined and failed replication in subsequent studies (18–20). Among genes identified in candidate studies are receptors for detection of microbial products (TLRs, *CD14*, *CARD15*, among others); various cytokines and cytokine signaling proteins involved in T-cell survival, proliferation, and differentiation; genes involved in lung function, development, and response to stimuli (*ADRB2*, *CFTR*, *SPINK5*, etc.); genes involved in epithelial barrier function and innate immunity (*FLG* and *DEFB1*) (21,22); and genes believed to be involved in the responses to environmental exposures (*GSTM1*, *GSTP1*, and *GSTT1*) (19,23–25). Genes that have been extensively replicated include the beta2 adrenergic receptor gene (26–28); the cytokines, receptors, signaling proteins, and transcription factors involved in  $T_H1$  and  $T_H2$  differentiation of T cells, such as *IL4*, *IL4RA*, *IFNG*, *IFNGR1*, *STAT6*, *GATA3*, and *TBX21* (29–36); and genes involved in the cellular responses that characterize atopic disease, such as *IL13* and its receptor and the *FCER1B* gene (37–41). Genes that have been identified in five or more candidate gene studies as having a positive association with asthma, or asthma-related phenotypes, are listed in Table 59-1.

**TABLE 59-1 Summary of Well-Replicated Loci Identified Through Candidate Gene Studies**

Gene	Chromosomal Locus	Function
Immune function		
<i>IL10</i>	1q31-q32	Cytokine—immune regulation
<i>CTLA4</i>	2q33	Control/inhibition of T-cell responses/immune regulation
<i>IL13</i>	5q31	Induces T <sub>H</sub> 2 effector functions
<i>IL4</i>	5q31.1	T <sub>H</sub> 2 differentiation
<i>CD14</i>	5q31.1	Microbe detection—recognizes pathogen-associated molecular patterns
<i>HAVCR1</i>	5q33.2	T-cell responses—hepatitis A virus receptor
<i>LTC4S</i>	5q35	Leukotriene synthase—inflammatory mediator
<i>LTA</i>	6p21.3	Inflammatory mediator
<i>TNF</i>	6p21.3	Inflammatory mediator
<i>HLA-DRB1</i>	6p21	Major histocompatibility complex class II—antigen presentation
<i>HLA-DQB1</i>	6p21	
<i>HLA-DPB1</i>	6p21	
<i>FCER1B</i>	11q13	Receptor for IgE—atopy
<i>IL18</i>	11q22.2-q22.3	Inflammation
<i>STAT6</i>	12q13	IL-4 and IL-13 signaling
<i>CMA1</i>	14q11.2	Chymase—mast cell expressed serine protease
<i>IL4R</i>	16p12.1-p12.2	Alpha chain of receptors for IL-4 and IL-13
Barrier function/innate immunity		
<i>FLG</i>	1q21.3	Epithelial integrity and barrier function
<i>SPINK5</i>	5q32	Epithelial serine protease inhibitor
<i>CC16</i>	11q12.3-q13.1	Potential immunoregulatory function—epithelial expression
<i>NOS1</i>	12q24.2-q24.31	Nitric oxide synthase—cellular communication
<i>CCL11</i>	17q21.1-q21.2	Eotaxin-1: eosinophil chemoattractant
<i>CCL5</i>	17q11.2-q12	RANTES: chemoattractant for T cells, eosinophils, basophils
Tissue response		
<i>GSTM1</i>	1p13.3	Detoxification, removal of products of oxidative stress
<i>ADRB2</i>	5q31-q32	Smooth muscle relaxation
<i>GPRA</i>	7p14.3	Regulation of metalloprotease expression, neuronal effects
<i>NAT2</i>	8p22	Detoxification
<i>GSTP1</i>	11q13	Detoxification, removal of products of oxidative stress
<i>ACE</i>	17q23.3	Regulation of inflammation
<i>TBXA2R</i>	19p13.3	Platelet aggregation
<i>TGFB1</i>	19q13.1	Influences cell growth, differentiation, proliferation, apoptosis
<i>ADAM33</i>	20p13	Cell–cell and cell–matrix interactions
<i>GSTT1</i>	22q11.23	Detoxification, removal of products of oxidative stress

Genes identified as asthma susceptibility loci in candidate gene studies. Genes are grouped loosely based on their functions in immunity, epithelial barrier function, or tissue response and remodeling.

**59.2.1.2 Linkage Studies.** Genome-wide linkage study design focuses on families affected by the disease of interest. With less genetic recombination occurring between closely related individuals, it is possible to screen the entire genome with a panel of relatively few, evenly spaced markers, searching for variants that are either unique to or over-represented in affected individuals. If such a region is found, it is said to be linked with the disease trait, and the genes within this region can become candidates for further analysis, including association study followed by positional cloning of the gene. Unlike the candidate gene association study, this study design allows for the identification of genes and pathways previously not suspected of contributing to the disease in question. However, because large families of affected individuals are needed, these studies are expensive and difficult to conduct. Moreover, while they are effective at

identifying genes with low-frequency variants with high penetrance and large effects, they often lack the statistical power to identify genes of modest effect that are attributed to common alleles. This is in contrast to genome-wide association studies (discussed later), which are best suited to the identification of common variants with lower penetrance and smaller effects. In this way, linkage studies and association studies are used to address different questions, and are, in fact, complementary.

Approximately 20 genome-wide linkage screens have been reported in different populations investigating chromosomal regions that are linked to asthma and atopy, or related phenotypes such as elevated IgE levels, wheezing, and BHR. A number of chromosomal regions have been repeatedly identified across multiple studies that contain genes of biological relevance to asthma and allergic disease, including the cytokine cluster on chromosome

**TABLE 59-2** Table of Loci Identified through Linkage Studies and Positional Cloning

Gene	Chromosomal Locus	Reference
<i>CYFIP2</i>	5q33.3	Noguchi et al., 2005 (42)
<i>DPP10</i>	2q14.1	Allen et al., 2003 (43)
<i>HLA</i>	6p21.33	Nicolae et al., 2003 (44)
<i>PHF11</i>	13q14.3	Zhang et al., 2003 (45)
<i>GPRA</i>	7p14.3	Laitinen et al., 2003 (46)
<i>ADAM33</i>	20p13	Van Eerdewegh et al., 2003 (47)

5q (containing interleukin-3 (*IL3*), *IL5*, and granulocyte/macrophage colony-stimulating factor (*GMCSF*)), *FCER1B* on 11q, *IFNG* (interferon  $\gamma$ ) and *STAT6* on 12q, and *IL4R* (the IL-4R $\alpha$  chain, also part of the IL-13R) on 16p. Linkage studies followed by positional cloning approaches have resulted in the identification of a handful of novel asthma susceptibility genes, including *CYFIP2* (42), *DPP10* (43), *HLA* (44), *PHF11* (45), *GPRA* (46), and *ADAM33* (47). *GPRA* (G protein-coupled receptor for asthma) and *ADAM33* (a disintegrin and metalloproteinase domain-containing protein 33) have generated considerable interest, as their expression in bronchial smooth muscle cells suggests roles in the pathobiology of asthma and pulmonary allergic disease (46).

**59.2.1.3 Genome-Wide Association Studies.** Rapid advances in microarray technology that now permit the high-throughput genotyping of hundreds of thousands of single nucleotide polymorphisms (SNPs) have allowed for the development of a third type of study, the genome-wide association study (GWAS). In this design many SNPs (hundreds of thousands) are compared across the entire genome between cases and controls. Like the candidate gene association study, this design requires the collection of a large number of cases and controls for analysis, to achieve statistical power. In contrast to the candidate gene approach, however, it permits a hypothesis-free search for gene variants associated with disease, revealing new targets for researchers. As mentioned earlier, GWAS is well suited for discovery of common alleles with relatively small effects. The results of GWAS targeting asthma or related phenotypes are summarized in Table 59-2.

In 2007, the first GWAS that focused on bronchial asthma as an end point was reported (48), and identified multiple markers on chromosome 17q21 reproducibly associated with childhood-onset asthma. The findings were replicated in German and British cohorts. Independent replication of the 17q21 association has been reported in multiple populations of diverse ethnic backgrounds (49–53).

Variable expression of two genes within this region, *ORMDL3* and *GSDML*, was linked to asthma susceptibility (48). *ORMDL3* is a member of a gene family that

encodes transmembrane proteins anchored in the endoplasmic reticulum (54). *GSDML* encodes a member of the gasdermin proteins that are expressed in epithelial cells and regulate apoptosis. Both sequencing and functional data will be required to identify the causal gene; however, this finding does represent the first step in unraveling the complex genetics underlying asthma susceptibility in a hypothesis-independent manner.

A case-control GWAS of North American asthmatics of European ancestry from the Childhood Asthma Management Program (CAMP) cohort has also been reported. No loci reached genome-wide significance in their discovery cohort, whereas the strongest association was to variants of the *PDE4D* gene on chromosome 5q12. In seven Caucasian replication cohorts, two of seven *PDE4D* SNPs were marginally associated. No significant associations were observed at the *PDE4D* locus in populations of African ancestry (55). *PDE4D* is a lung-expressed phosphodiesterase that has been implicated in airway contractility; as such it is a plausible asthma candidate gene that warrants further investigation. In a separate study, genome-wide association data from the CAMP cohort was investigated for replication of previously reported candidate gene associations. Approximately 30 genes were investigated with five SNP-based associations replicating to a nominal significance in the *IRAK-3*, *PHF11*, *IL10*, *ITGB3*, and *IL4R* genes (56).

Another GWAS on allergic asthma was recently reported, with children 6 years of age, whose mothers had participated in an earlier study of asthma in pregnancy (Perinatal Risk of Asthma in Infants with Asthmatic Mothers—PRAM). An initial genome-wide association screen was performed on small numbers of cases and controls of mixed ethnic descent, and the most significant SNPs were further analyzed in a larger collection of samples. Although no single SNP achieved genome-wide significance, one SNP in an intron of *PDE11A* was cited as potentially interesting. *PDE11A* encodes a phosphodiesterase related to *PDE4D*, suggesting that this family of proteins may play a broader role in asthma pathogenesis (57).

A genome-wide association was also reported on two independent populations of African descent ascertained through the Genomic Research on Asthma in the African Diaspora (GRAAD) consortium, which included African-American asthmatics and controls from the Baltimore-Washington, DC, area and African Caribbean asthmatics and their family members from Barbados (58). A meta-analysis of the two populations did not yield any genome-wide significant associations, illustrating the complexity of identifying associations for a complex disease in admixed and heterogeneous populations.

An association was reported between several SNPs in the transducin-like enhancer of split 4 (*TLE4*) gene on chromosome 9q with asthma in a population of 492 Mexican children with asthma, but these associations also did not reach genome-wide significance (59).

However, the investigators replicated these findings in an independent cohort of 177 Mexican case-parent trios. *TLE4* had not previously been linked to the pathogenesis of asthma, but does play a role in early B-cell development (60).

Association of asthma with SNPs in multiple genes was reported in a recent study containing more than 10,000 individuals with physician-diagnosed asthma and 16,000 unaffected persons matched for ancestry (61). SNPs in several loci achieved genome-wide significance, including a block on chromosome 2 that includes *IL1RL1* and *IL18R*, *HLA-DQ* on chromosome 6, *IL33* on chromosome 9, *SMAD3* on chromosome 15, and *IL2RB* on chromosome 22. The authors observed association with the previously reported *ORMDL3/GSDMB* locus on chromosome 17 only in childhood-onset asthma. Many of these genes have direct or indirect roles in T-cell responses (*IL2RB*, *HLA-DQ*) and the development of T<sub>H</sub>1 (*IL18R1*) or T<sub>H</sub>2 (*IL33*) responses. *SMAD3* is involved in the response to transforming growth factor  $\beta$ , which controls proliferation, differentiation, and apoptosis depending on the cellular context.

A GWAS from our group was recently reported on a series of pediatric asthma patients consisting of North American cases of European ancestry with persistent asthma requiring daily inhaled glucocorticoids for symptom control, and matched controls without asthma. In addition to the previously reported 17q21 locus, we uncovered association to a novel asthma locus on chromosome 1q31 in the discovery cohort and replicated the finding in an independent cohort of Northern European ancestry. The locus contains *DENND1B*, a gene that is expressed by natural killer (NK) cells and dendritic cells (62). Homologs of the *DENND1B* protein have been shown to interact with the TNF $\alpha$  receptor (63). To determine whether the 1q31 locus also contributes to asthma in children of African ancestry, we also tested for association of the chromosome 1q31 locus and asthma in African-American cases and ancestrally matched controls. A total of 17 of 20 SNPs were significantly associated with asthma, although the associated allele at each SNP was the alternative allele to that associated with asthma in the discovery set. Allele reversal at shared risk loci can be attributed to differences in the underlying genomic architecture at the loci between populations of different ancestry and as a result is being tagged differently. The *DENND1B* gene has since been replicated in inflammatory bowel disease, in separate studies of both Crohn disease and ulcerative colitis, and in primary biliary cirrhosis.

Six GWAS have been reported using intermediate phenotypes and quantitative traits, rather than asthma itself, as study end points. The first report used genome-wide associations to identify variants that modulate serum protein levels (64). A promoter SNP in the *CHI3L1* gene that encodes the chitinase-like protein YKL-40 was shown to influence serum YKL-40 levels and was also shown to be weakly associated with asthma, bronchial responsiveness,

and pulmonary function in the Hutterite population. A GWAS showed significant association of the *FCER1A* and *RAD50* genes with expression of CHI3L1, and evidence for association of the *STAT6* gene with IgE levels. IgE levels are closely correlated with the clinical expression and severity of both asthma and allergy. The *RAD50* variants were further shown to be associated with increased risk of asthma and atopic eczema (65).

Eosinophils are leukocytes that play an important role in the initiation and propagation of inflammatory signals. This makes them likely mediators of inflammatory disease and a GWAS was performed examining blood eosinophil counts. Five loci reached genome-wide association significance, one of which, *IL1RL1*, was also shown to be associated with asthma in a collection of 10 different populations (66).

One GWAS focused on chronic obstructive pulmonary disease (COPD), and three other studies performed GWAS on lung function using a quantitative metric of lung function as a measure of airflow obstruction. Altered lung function, and airflow obstruction in particular, is associated with both asthma and COPD. Two SNPs at the  $\alpha$ -nicotinic acetylcholine receptor (*CHRNA 3/5*) surpassed genome-wide significance in the study and replicated in two of three independent cohorts. The *CHRNA 3/5* locus had previously been associated with lung cancer and nicotine dependence (67,68). The authors also reported that SNPs at the *HHIP* locus on chromosome 4 showed association and were consistently replicated across the study cohorts but did not reach genome-wide significance (69). In the first of the three lung-function GWAS that included 7691 Framingham Heart Study participants, the only locus to surpass genome-wide significance for association with FEV<sub>1</sub>/FVC ratio and replicate in an independent cohort of 835 Family Heart Study participants was *HHIP* (152).

The final two studies resulted in the identification of eleven novel loci associated with measures of lung function; both studies also replicated the previously reported association of the *HHIP* locus (70,71). These novel loci will not only shed further light on the pathways associated with pulmonary function but may also provide potential targets for respiratory disease such as asthma and COPD.

## 59.2.2 Themes Revealed by Genetic Analysis of Asthma Susceptibility

The numerous genome-wide linkage, candidate gene, and genome-wide association studies performed on asthma and asthma-related phenotypes have resulted in an increasingly large list of genes implicated in asthma susceptibility and pathogenesis. This list can be categorized into four broad functional groups (19,72–74), from which several themes have emerged, as summarized in Figure 59-1.

**59.2.2.1 T<sub>H</sub>2-Mediated Cell Response.** T<sub>H</sub>2-cell-mediated adaptive immune responses have been widely recognized as a crucial component of allergic disease.

**FIGURE 59-1** Genes implicated in asthma susceptibility and pathogenesis.

Genes involved in T<sub>H</sub>2-cell differentiation and function have been extensively studied in asthma candidate gene association studies, and as one might expect, SNPs in many of these genes have been associated with asthma and other allergic phenotypes. Genes important for T<sub>H</sub>1 versus T<sub>H</sub>2 T-cell polarization, such as *GATA3*, *TBX21*, *IL4*, *IL4RA*, *STAT6*, and *IL12B*, have been implicated in asthma and allergy (29–38,75,76). The genes encoding IL-13 and the beta-chain of the IgE receptor FcεR1 are well-replicated contributors to asthma susceptibility (37,39–41,75,77). These two molecules play critical roles in allergic disease.

**59.2.2.2 Environmental Sensing and Immune Detection.** A second class of associated genes is involved in detection of pathogens and allergens. These genes include pattern recognition receptors and extracellular receptors, such as *CD14*, toll-like receptor 2 (*TLR2*), *TLR4*, *TLR6*, *TLR10*, and intracellular receptors, such as nucleotide-binding oligomerization domain containing 1 (*NOD1/CARD4*) (78–83). Additional studies identified variations in the human leukocyte antigen (HLA) class II genes associated with asthma and allergen-specific IgE responses (77). These molecules are important in the immune response and shaping of the T-cell repertoire;

their involvement in an immune-mediated inflammatory disorder like asthma is unsurprising.

**59.2.2.3 Tissue Response.** A variety of genes involved in mediating the response to allergic inflammation and oxidant stress on the tissue level appear to be important contributors to asthma susceptibility. Examples include *ADAM33*, a disintegrin and metalloprotease expressed in lung fibroblasts and smooth muscle cells; the alpha-1 chain of type 29 collagen (*COL29A1*); leukotriene C4 synthase (*LTC4S*); glutathione S-transferase (*GSTP1*, *GSTM1*); arachidonate 5-lipoxygenase (*ALOX-5*); and nitric oxide synthase 1 (*NOS1*) (47,84–90).

**59.2.2.4 Epithelial Barrier Function.** Studies of asthma genetics have raised new interest in the body's first line of immune defense, the epithelial barrier, in the pathogenesis of asthma. Mutations in the filaggrin gene (*FLG*) were initially identified in the rare single-gene disorder ichthyosis vulgaris (91), but subsequently loss-of-function variants were reported to be strongly associated with atopic dermatitis, eczema, and asthma, both dependent and independent of atopic dermatitis (22,92–94). Filaggrin, a protein involved in keratin aggregation, is not expressed in the bronchial mucosa (95), which has lead others to

suggest that asthma susceptibility in patients with loss-of-function *FLG* variants may be due to allergic sensitization that occurs after breakdown of the epithelial barrier (96).

Several epithelial genes with important roles in innate and adaptive immune function have also been implicated in asthma. These genes include defensin-beta1 (an antimicrobial peptide), uteroglobin/Clara cell 16-kD protein (*CC16*) (an inhibitor of dendritic cell-mediated  $T_H2$ -cell differentiation), and several chemokines (*CCL-5*, -11, -24, and -26) involved in the recruitment of T cells and eosinophils (21,97–102). Variations in *SPINK5*, a serine protease inhibitor limited to the epithelium and the causative factor in Netherton syndrome (103), have been associated with asthma, but with conflicting results (75,81,104,105).

### 59.2.3 The Future of Asthma Genetics

Many studies that have been aimed at asthma and allergies have revealed considerable new information about the genetic variants that underlie susceptibility to the condition as well as its severity. It is through this work that we have come to appreciate the importance of the barrier function of epithelium and molecules involved in the sensing and effector arms of innate immunity. In addition, we have a much better picture of the critical roles played by both  $T_H2$  skewing and the molecules involved in the development and remodeling of the lungs. The application of GWAS to asthma, with the possibility of discovering new genes that are currently unsuspected in asthma pathobiology, has the potential to greatly and rapidly expand our knowledge of the genetic and biological factors contributing to this complex genetic disease. However, challenges remain in the understanding of the genetic contribution to asthma and only a relatively small proportion of its heritability is explained despite recent advances. Although the other contributing factors are not necessarily specific to asthma genetics, they are worth illuminating here.

**59.2.3.1 Gene–Environment Interactions.** Asthma, as an immune-mediated disease, involves the response of the body to the environment, in the form of pollutants, allergens, viruses, and other pathogens and irritants. These environmental factors interact with genetic variation to influence the development or severity of disease. Researchers are finding that specific genetic variants affect susceptibility to, and the severity of, asthma in different ways depending on the environments of the individuals carrying those variants, a phenomenon known as gene–environment interaction. Several examples of gene–environment interaction exist in asthma, with perhaps the best characterized being *CD14*. Interest in *CD14* as an asthma susceptibility locus originates with linkage studies identifying an association between asthma (and related phenotypes) and chromosome 5q, where *CD14* is located (106–110). The protein product of *CD14* acts to optimize the immune response to pathogen-associated molecular pathogens, such as lipopolysaccharide (LPS)/endotoxin (111,112). This function made *CD14* an interesting candidate gene within the chromosome 5q region linked to asthma. A functional SNP

(denoted *CD14*-260C>T) in the promoter of *CD14* was associated with increased *CD14* protein levels in serum and reduced serum IgE levels (113,114). This polymorphism has been examined in candidate gene association studies of asthma, with conflicting results. Studies have demonstrated a protective role for the T allele at this SNP, including reduced serum IgE levels and allergic symptoms in individuals bearing this allele (115,116). Conversely, other studies showed that the T allele does not protect from asthma or allergy, with association of this allele with higher IgE levels in laboratory workers (117), increased positive skin tests (118), and food allergies (119) in different study populations. In two German cohorts, *CD14*-260T was not associated with asthma, atopy, or IgE levels (120,121). The reasons for such conflicting results were unclear, until studies of potential environmental influences were performed. The *CD14*-260C allele was associated with higher IgE levels in children with pets like cats and dogs, while the opposite allele was associated with the same phenotype in children exposed to stable animals such as horses (122). Homozygotes for *CD14*-260T were found to be at lower risk for asthma if exposed to comparatively low levels of house dust endotoxin, but at higher risk at higher endotoxin exposures (123). These alleles have opposite effects on allergic reactions in individuals of Karelian ethnicity that live in either Finland or Russia (124), suggesting key environmental differences between these locales. This SNP has also been associated with effects on IgE by alcohol consumption (125) and *Helicobacter pylori* (126). Other polymorphisms at the *CD14* locus have been associated with different outcomes in specific populations, depending on environmental exposure (117). Given the large number of identified asthma susceptibility loci, and the daunting amount of environmental variables that may influence complex diseases, much work remains before we have a reasonable understanding of the roles of gene–environment interactions in asthma.

**59.2.3.2 Gene–Gene Interactions.** A comparatively small number of studies have been published to date examining the role in asthma of gene–gene interactions, where variation at one locus alters the effects of variations at a second locus, reflecting epistasis between two or more genes. The existing literature consists mainly of studies in which researchers have chosen two or more specific genes (and occasionally specific variants of those genes) to examine in the context of asthma, looking for evidence of interactions between the two loci. Examples of gene–gene interactions that have been observed in association with asthma include *IL9* and *IL9R* polymorphisms in Koreans (127), *TGFBR2* and *FOXP3* in specific IgE production (128), *IL13* and *IL4* in Dutch cohorts (129), and *LTA4H* and *ALOX5AP* in Latinos (90). Larger scale analysis examining 169 SNPs in 29 genes identified a number of gene–gene interactions affecting both total and antigen-specific IgE levels (130). Methods are actively being developed to enable large-scale and unbiased analysis of gene–gene interactions (131) and visualization of the resulting networks (132), but these

efforts are in their relative infancy. Given the number of previously identified relevant genes, and the possibilities for discovery of new loci, the combinatorial potential for interactions between gene effects is daunting. Much work remains in the development of methods and tools before we will truly grasp these vast possibilities.

**59.2.3.3 Replication.** It has been a long-term concern for the field of asthma genetics (and for the study of many other common, complex diseases) that many discoveries fail to be replicated in subsequent studies (133,134). While concerns about poorly constructed or statistically underpowered studies are constant, an appreciation has developed for other issues that may affect study results (135). Heterogeneity among cases and controls is the most basic confounder of genetic analyses. While tools have been developed to address the most obvious source of heterogeneity, racial and ethnic diversity (136–138), other less apparent sources may remain. As described earlier, asthma is influenced by gene–environment interactions, with genetic and environmental variability interacting in unexpected ways. The search for statistical power has led to studies with increasingly large sample sizes; large populations are required to detect the common variants with small effect sizes that are hypothesized to underlie complex diseases like asthma. However, these growing study populations carry risks as well as benefits, as it becomes more difficult to account for diversity among large populations. While computational tools exist to deal with racial stratification in study groups, less attention has historically been paid to geographic and environmental diversity. And while genetic analyses like GWAS often inherently include the information required to identify racial stratification, accounting for environmental variations requires additional effort in the form of questionnaires or surveys answered by study participants, or observation and sampling of the participants' environments. These concerns may directly affect the issue of replication, as the assembly of ever larger cohorts may result in the mixing of environmental influences, diluting the effects of gene–environment interactions and making the detection of the connected loci difficult if not impossible. In fact, the example of *CD14* described earlier demonstrates that studies focused on smaller groups can yield informative results, if the smaller cohorts are accompanied by reports on environmental influences. However, in the case of asthma the list of environmental influences may be extraordinarily long. Endotoxin, various allergens, cigarette smoke, airborne pollutants, and indoor pets or stable animals have all been considered environmental factors for asthma, as have less obvious connections, such as whether and for how long an infant was breast-fed (139,140). Controlling for these impacts will be increasingly laborious, and lack of accounting for some of these factors may account for failures of genes to be replicated.

Replication in asthma studies faces an additional complication in the varying phenotypes that can be considered asthma-associated, and the degree to which a specific locus needs to be identified to be considered replicated. Both phenotypes and genotypes can be subjected to varying

stringent criteria, generally referred to as strict or loose replication (141). For phenotypes, strict replication would involve studies that consider only the same end point (i.e. diagnosis of asthma, BHR, serum IgE levels, allergic skin test responses), while loose replication would consider studies that identified the same locus using varying but related end points. For genotypes, strict replication would require identification of precisely the same variant of a gene (SNP, copy number variation, insertion or deletion) in multiple studies, while loose replication considers the gene itself to be the unit of replication, including all variants identified at a locus. Use of the gene as the unit of replication has been advocated (18,142), and is becoming more common, but worries persist that this is too permissive a standard and may lead to inappropriate conclusions of replication (141). Obviously, convincing demonstration of replicated results will be difficult if researchers cannot agree on even the standard of replication required.

**59.2.3.4 Pharmacogenetics.** Pharmacogenetics, in which variations in genotype are examined for their effects on the response to treatments, is of growing interest with asthma, with the hope that it will increase efficacy and reduce toxic side effects of medications. It is a nascent field, and as such there are still few studies that involve more than a few hundred subjects, and most are limited to only one or two candidate genes selected for their known or suspected roles in response to specific medication. The best example at this time is provided by beta-adrenergic receptor agonists (or simply beta-agonists), which are prescribed to treat bronchoconstriction and provide long-term symptom control for asthmatics. The *ARDB2* locus encodes the beta<sub>2</sub>-adrenergic receptor, which binds to and is activated by beta-agonists. This activation leads to several downstream effects, including relaxation of airway smooth muscle, thereby alleviating the acute symptoms of an asthma attack. Two studies have implicated variations in *ARDB2* as modulators of response to inhaled bronchodilators (143,144). However, a recent randomized, double-blind study was performed in which subjects were genotyped before being enrolled, so that they could be stratified by genotype before receiving prescriptions (145). This study showed no association of genotype with the response to beta-agonists. One study showed that an arginine/glycine polymorphism at position 16 of the *ARDB2* protein influences the response to regularly administered albuterol, with the Arg/Arg genotype receiving less relief from regular, long-term use of short-acting beta-agonists (146). Yet another group has shown that genotype *ARDB2* does not affect the response to combined beta-agonist and inhaled corticosteroid treatment (147).

While several other genes that are targeted by current asthma treatments have been identified as asthma susceptibility loci, very few have actually been analyzed for the effects of variations in genotype on treatment. Genes involved in the biosynthesis of leukotrienes, such as *ALOX-5*, *ALOX5AP*, and *LTC4S*, have been identified as asthma susceptibility loci; drugs targeting the leukotriene pathway, such as 5-lipoxygenase inhibitors

and cysteinyl leukotriene receptor 1 antagonists, have been approved for treatment of asthma. One group has shown that variations at *ALOX5* correlate with the response to a 5-lipoxygenase inhibitor (148), while another demonstrated that an SNP in the gene *LTA4H*, which encodes a leukotriene cleaving enzyme (LTA<sub>4</sub> hydrolase), associates with variability in the response to a cysteinyl leukotriene receptor 1 antagonist (149). Two studies have shown that variants of genes involved in the synthesis of or the response to glucocorticoids impact the response to inhaled glucocorticoids in asthmatics. Polymorphisms in corticotrophin-releasing hormone receptor (*CRHR1*) (150) and the *STIP1* gene (involved in the signaling initiated by glucocorticoids) (151) associate with variable FEV<sub>1</sub> response after

inhaled glucocorticoid treatment, as do polymorphisms in *TBX21*, encoding a transcription factor important in the generation of T<sub>H</sub>1 cells (35). This last study demonstrates that variations in genes not directly involved in the metabolism or signaling cascades of a drug can be important modulators of the response to that drug. This point will be critical in the future of pharmacogenetics, as researchers design the studies and tools necessary to examine drug–gene interactions in an unbiased way. Just as GWAS and linkage studies allow identification of susceptibility loci that would not have been suspected based on known function, unbiased pharmacogenetic studies could allow identification of variants that affect the response to treatment that cannot be predicted based on current information (Table 59-3).

### 59.3 CONCLUSION

Despite the progress that has been made in understanding the genetic contribution to asthma and allergic disease in recent years, much work remains to be done before this information can be used to improve the diagnosis and management of individuals suffering from these conditions. Today's discoveries unfortunately only explain a fraction of the heritability of asthma. Referred to as "missing heritability," this difficult-to-fill void in our understanding has become a common theme in the analysis of complex genetic traits. As more GWAS of increasingly greater size are performed, it is likely that additional loci will be identified that will close a portion of this gap. However, GWAS are not well suited to the detection of rare variants with potentially large effects. More importantly, the development of techniques to describe gene–gene and gene–environment interactions, which likely play a key role in the susceptibility to allergic disease, is only in its infancy. Very little is known how epigenetic phenomena, heritable but reversible changes to DNA (such as methylation) that are not detected by standard genotyping, may contribute to asthma and allergy pathogenesis. Advancement in sequencing technologies is likely to enable strategies capable of thoroughly examining the entire genome, including all genetic and epigenetic variations and their complex interaction. Together with transcriptome sequencing and in silico, in vitro, and in vivo models of human-derived tissues through induced pluripotent stem (IPS) cell cultures, eventually we will be able to complete the journey from genetic discovery to improvements in asthma patient care.

## Biographies

**Hakon Hakonarson, MD, PhD**, is an associate professor of Pediatrics at The University of Pennsylvania School of Medicine. He is a physician-scientist and pediatric pulmonologist by training and director of The Children's Hospital of Philadelphia's Center for Applied Genomics (CAG), a high-throughput highly automated genotyping facility founded to identify the genetic causes of complex medical disorders in children, such as autism and cancer, with the objective of developing new therapies. The Center represents a \$40 million commitment from CHOP to genotype approximately 100,000 children, a research undertaking that has gained nationwide attention, including news features in the *Wall Street Journal*, *New York Times*, *Time Magazine*, *Nature* and *Science*. Dr Hakonarson has an extensive track record in human genetics and has developed an international reputation among his peers. He has served previously in several senior posts in the biopharmaceutical industry, including as the Director of Inflammatory and Pharmacogenomics Research and the Vice President of Clinical Sciences and Development and CSO. Dr Hakonarson has also been the principal and co-principal investigator on several NIH-sponsored grants, and he has published numerous high-impact papers on genomic discoveries and their translations in some of the most prestigious scientific medical journals, including *Nature*, *Nature Genetics* and *The New England Journal of Medicine*. *Time Magazine* listed Dr Hakonarson's autism gene discovery reported in *Nature*, 2009, among the top 10 medical breakthroughs of that year. With over 10 years of experience in pioneering genomics research and genome-wide mapping and association studies in asthma and other complex diseases, Dr Hakonarson has intimate knowledge of the complexities of large-scale genomics projects and has put together the necessary infrastructure and workflow processes to unravel these complexities.

**Michael E March, PhD**, is a research scientist at The Children's Hospital of Philadelphia's Center for Applied Genomics (CAG). He earned his PhD in microbiology from the University of Virginia in 2003 for research into the molecular mechanisms of Fc-receptor-mediated inhibition of antigen stimulation in B cells, in the laboratory of Kodimangalam S. Ravichandran, PhD. He served as a postdoctoral fellow in the laboratory of Eric O. Long, at the National Institute for Allergy and Infectious Diseases, where he engagement. Since joining CAG in 2010, Dr March has undertaken the molecular characterization of *DENND1B*, a molecule identified by Dr Patrick Sleiman, colleagues in CAG, and a host of collaborators as a novel asthma susceptibility gene with unknown mechanisms for influencing asthma or immune function.

**Patrick M A Sleiman, PhD**, is currently Assistant Professor of Pediatrics at the Children's Hospital of Philadelphia and the University of Pennsylvania Medical School. He obtained a PhD in genetics from University College London and was subsequently a postdoctoral research fellow at the Institute of Neurology in London and then at the Center for Applied Genomics in Philadelphia. His research interests are in identifying the genetic basis of Mendelian and complex human disease, specifically within the domains of asthma and allergies, neurodevelopment and neurodegeneration. Dr Sleiman has been involved in the discovery of several novel disease genes in asthma, Parkinson's disease and dementia and has authored over 70 peer-reviewed publications.

### 60.1 INTRODUCTION

Pulmonary emphysema has been a recognized clinical problem since Bonet described the condition of “voluminous lungs” in 1679. The first description of enlarged airspaces in emphysema was by Ruysh in 1721, and Baillie described the destructive character of the condition in 1789, which was followed by the comprehensive description by Laennec in 1819 (1). In the 1893 edition of his *Principles and Practice of Medicine*, Osler described several forms of

emphysema, including hypertrophic emphysema, which involved “distention of the air-cells and atrophy of their walls, and clinically by the imperfect aeration of the blood and more or less marked dyspnoea” (2). In addition to this remarkably modern description of emphysema, Osler noted “the markedly hereditary character of the disease.”

Chronic obstructive pulmonary disease (COPD) includes emphysema and chronic bronchitis. Because emphysema is encompassed within the diagnostic rubric of COPD, we focus our discussion on COPD in general and only refer to emphysema when specifically warranted. Since the mass production of cigarettes began in the early 1900s, the development of COPD has become increasingly common. COPD is the fourth leading cause of morbidity and mortality in the United States and is expected to rank third as the cause of death worldwide by 2020 (3). There are estimated to be 10 million individuals in the United States with physician-diagnosed COPD and many more affected individuals who are undiagnosed (4).

Although case reports of familial COPD were published in the 1950s (5), interest in the role of genetic factors in COPD largely began with the discovery of severe alpha 1-antitrypsin (AAT) deficiency by Laurell and Eriksson in 1963 (6). AAT deficiency is a proven genetic determinant of COPD; therefore, we discuss the molecular and population genetics of AAT deficiency in detail. In addition, we review the evidence for genetic factors in non-AAT deficiency COPD, including assessment of risk to relatives, segregation analysis, linkage analysis, and association studies. We also discuss the utility of animal models in identifying the genetic determinants of COPD.

### 60.2 DISEASES WITH AIRFLOW LIMITATION: DEFINITIONS

Pulmonary emphysema is included with chronic bronchitis and small airway disease in the syndrome of COPD. COPD is defined as a “disease state

characterized by airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases” (7). Thus, airflow limitation, also known as airflow obstruction, is central to the definition of COPD. In addition to chronic bronchitis, emphysema, and small airway disease, COPD has also been used to describe the subset of asthmatic subjects who have chronic airflow obstruction as well as subjects with less common conditions such as bronchiectasis. For this discussion, we restrict COPD to include individuals with chronic bronchitis, small airway disease, and/or pulmonary emphysema.

### 60.2.1 Pulmonary Emphysema

Pulmonary emphysema is an anatomically defined condition characterized by abnormal airspace enlargement and destruction of airspaces beyond the terminal bronchioles but without obvious fibrosis (8). This destructive process reduces elastic recoil of the lung, accounting for airflow obstruction. In addition, the surface available for gas exchange is reduced, which, in severe cases, limits the capacity for gas exchange to occur and results in hypoxemia. A cross-section of an emphysematous lung is shown in Figure 60-1.

### 60.2.2 Chronic Bronchitis

Chronic bronchitis is a condition defined on a clinical basis by the presence of cough productive of phlegm for at least 3 months per year for at least two consecutive years (8). This excess mucus production should not be caused by other conditions, such as bronchiectasis or tuberculosis. Subjects with chronic bronchitis frequently do not have chronic airflow obstruction; for this discussion, we consider individuals with chronic bronchitis to have COPD only if they also have chronic airflow obstruction.

### 60.2.3 Small Airway Disease

COPD also includes small airway disease—a poorly understood entity that includes inflammation of the terminal and respiratory bronchioles as well as fibrosis of airway walls with narrowing (8). Some inflammation of the terminal and respiratory bronchioles is likely present in all cigarette smokers. However, only a subset of smokers develops fibrosis and narrowing of the small airways, with associated airflow obstruction.

The classification of disease processes encompassed within COPD emphasizes the heterogeneity of this disorder. Some investigators have attempted to define subsets of COPD based on clinical and/or physiological criteria. For example, Burrows suggested that chronic airflow obstruction included a group of patients with

**FIGURE 60-1** Paper mounted whole lung section from a subject who died with COPD. This subject had severe emphysema, which was primarily the centrilobular form. Destruction of respiratory bronchioles produced increased airspaces throughout the lung. (From Thurlbeck et al., 1970 (246).)

emphysema, who were largely male smokers with progressive airflow limitation, and a group of patients with chronic asthmatic bronchitis, who were largely female with a more benign clinical course (9). However, dissection of the syndrome of COPD will likely require improved understanding of the pathophysiological basis of disease, and, potentially, the genetic determinants of this condition (10).

## 60.3 PHENOTYPIC EVALUATION IN COPD

A variety of phenotypes are useful in genetic and epidemiologic studies of COPD, including pulmonary function test data, chest computed tomography (CT) scan measurements, and questionnaire-derived assessments of respiratory symptoms. Development of biochemical markers that relate to the pathophysiology of COPD has been less successful.

### 60.3.1 Pulmonary Function Tests

As noted above, fixed airflow obstruction is essential for the definition of COPD. Airflow obstruction is typically determined by spirometry, which includes forced expiratory maneuvers after the subject has inhaled to total lung capacity. Key phenotypes obtained from spirometry include the volume of air exhaled within the first second of the forced expiratory volume in 1 s (FEV<sub>1</sub>) and

**FIGURE 60-2** Hypothetical tracking curves of FEV<sub>1</sub> which can lead to COPD. The normal pattern of growth and decline in FEV<sub>1</sub> is shown by curve a. Significant reductions in FEV<sub>1</sub> (below a threshold of 65% predicted) can occur by: (1) normal rate of decline after a reduced maximally attained FEV<sub>1</sub> (curve b); (2) early initiation of FEV<sub>1</sub> decline following normal growth (curve c); and (3) accelerated decline in FEV<sub>1</sub> following normal growth (curve d). (From Rijcken, 1991 (17).) B. Bronchial responsiveness and COPD risk: An epidemiological study (postdoctoral dissertation). (Adapted from Fletcher and Peto, 1977 (16).)

the total volume of air exhaled during the entire maneuver (forced vital capacity [FVC]). Subjects with airflow obstruction have a reduced ratio of FEV<sub>1</sub>/FVC; however, in addition to COPD, airflow obstruction can result from other diseases, such as asthma. Spirometric values are typically expressed as a percentage of predicted values, to adjust for known effects of age, gender, height, and ethnicity on these parameters.

In normal subjects, maximally rapid vital capacity (i.e. FVC) is equal to the relaxed or slow vital capacity (SVC). In subjects with significant airflow limitation, SVC is often larger than FVC because airways in such subjects tend to close before the lung region that they serve has fully emptied. Therefore, airflow obstruction may be more sensitively determined by the use of the FEV<sub>1</sub>/SVC rather than FEV<sub>1</sub>/FVC. Other spirometric measures, such as the forced expiratory flow rate between 25% and 75% of the FVC (FEF<sub>25-75</sub>), may also be used as phenotypes in the study of COPD. Some investigators contend that FEF<sub>25-75</sub> reflects obstruction in small airways, but the large coefficient of variation associated with this measurement may limit its utility.

Reduced FEV<sub>1</sub> has been repeatedly demonstrated to be a major risk factor for mortality from chronic lung disease (11,12) and from all causes (13,14). Since reduced FEV<sub>1</sub> can result from restrictive lung diseases (e.g. interstitial lung diseases, neuromuscular diseases) as well as obstructive lung diseases, analysis of the FEV<sub>1</sub>/FVC ratio selects for conditions associated with airflow obstruction. The relationship between emphysema and airflow obstruction is controversial; some investigators suggest that emphysema is not the major cause of airflow obstruction in COPD (15).

FEV<sub>1</sub> is particularly valuable in the assessment of COPD because it tends to track consistently throughout the life of an individual. FEV<sub>1</sub> follows a pattern of growth, plateau, and then decline with increasing age. There are at least three mutually independent ways that one can reach a low level of FEV<sub>1</sub> in later adult life.

Specifically, one can have reduced growth, premature decline, or accelerated decline in lung function. A simplified graphic depiction of the natural history of COPD is shown as a function of the influences on tracking curves of FEV<sub>1</sub> in Figure 60-2 (16,17). Death or disability can result from normal rate of decline after a reduced growth phase (curve b), early initiation of pulmonary function decline after normal growth (curve c), or accelerated decline after normal growth (curve d). The rate of decline can be modified by changing environmental exposures (i.e. quitting smoking), with smoking cessation at an earlier age leading to a more beneficial effect than smoking cessation after disability has developed.

Although rare individuals may experience precipitous declines in pulmonary function values, most individuals follow a steady trajectory of increased pulmonary function with growth during childhood and adolescence, followed by gradual decline with aging (18,19). Children appear to track in their quantile of pulmonary function based on environmental, developmental, and familial factors that put them on different tracks at an early age.

In addition to spirometry, other pulmonary function tests demonstrate abnormalities in COPD. Patients with emphysema tend to have increased total lung capacity and residual volume, related to the hyperinflation that accompanies alveolar destruction. Reduced diffusing capacity for carbon monoxide (DLCO) is also frequently noted in emphysema. However, DLCO is not reduced in some subjects with emphysema, and DLCO may be reduced in subjects with small airway disease rather than emphysema (20,21). A variety of pulmonary function tests were developed to assess early small airway disease, in an effort to identify a susceptible subpopulation of cigarette smokers who would develop severe COPD; such measurements, including the closing volume, tended to be abnormal in all smokers and were not useful in the identification of susceptible smokers (22).

### 60.3.2 Chest CT

The development of high-resolution CT (HRCT) chest scans has provided a powerful, noninvasive tool for assessment of the anatomic presence of emphysema. HRCT scans are much more sensitive than conventional chest X-rays for the detection of emphysema. High-resolution (thin cut) images allow identification and quantification of the extent of emphysema, which was not possible with conventional (thick cut) chest CT scan images (23). An example of the improved detection of emphysema by HRCT compared with conventional chest CT is shown in Figure 60-3.

Both qualitative (presence/absence or severity scales determined by radiologist scoring) and quantitative (computerized image analysis) approaches have been used to analyze the severity and distribution of emphysema on HRCT. Radiologist scoring typically involves grading the severity of emphysema in different lung regions and obtaining an overall emphysema score; independent scoring by multiple radiologists probably improves the quality of the emphysema scoring data. Using computerized

image analysis of the frequency distribution of X-ray attenuation values within the lung, thresholds can be defined corresponding to the presence of emphysema, and the fraction of lung below those thresholds can be used to assess the percentage of emphysema within the lung (24,25). Furthermore, Gupta et al. demonstrated that various quantitative and qualitative HRCT features correlate with patients' characteristics, spirometric indices, and health-related quality-of-life score, suggesting that HRCT is useful not only in detecting emphysema and its various subtypes but also in predicting the extent and severity of COPD (26).

Assessment of small airway disease using chest CT scanning has been quite challenging because the small airways responsible for airflow obstruction in COPD (<2 mm in internal diameter) are below the resolution of current chest CT scanners (27,28). However, Nakano et al. have shown that measurements of larger airways reflect the degree of remodeling in the small airways (29).

Kitaguchi et al. reported three COPD phenotypes based on HRCT evaluation: absence of emphysema, with little emphysema with or without bronchial wall thickening (A phenotype); emphysema without bronchial wall thickening (E phenotype); and emphysema with bronchial wall thickening phenotype (M-phenotype) (30). The presence of bronchial wall thickening in A- and M-phenotype groups was significantly associated with reversibility responsive to treatment with inhaled corticosteroid and sputum eosinophilia. These findings suggest that morphological phenotypes assessed by HRCT may help to evaluate the severity of COPD and identify patients who will respond to selective therapy. Although chest CT scanning holds great promise for COPD genetic studies, the optimal chest CT phenotypes for studies of COPD in general, and COPD genetic studies in particular, remain to be defined.

**FIGURE 60-3** Comparison of standard chest CT (image a) and high-resolution chest CT (image b) of a subject with severe AAT deficiency. Emphysema is not detected by standard chest CT, but regions of low-density and pulmonary vascular attenuation caused by emphysema are apparent on the high-resolution CT image. (From Guest and Hansell, 1992 (23).)

### 60.3.3 Questionnaire Phenotypes

A standardized questionnaire for evaluation of key epidemiological variables in respiratory studies was developed by the National Heart, Lung, and Blood Institute's (NHLBI) Epidemiology Standardization Project in 1978 (31). With minor modifications, the adult and children's versions of this questionnaire have been widely used in epidemiological and genetic studies of COPD. Questionnaire responses to items related to chronic cough and chronic phlegm production are essential for the clinical definition of chronic bronchitis; use of questions related to physician-diagnosed chronic bronchitis and physician-diagnosed emphysema are less accurate for the diagnosis of these conditions.

It is important to recognize that the physiological definition of COPD can be contrasted with the clinical criteria for the definition of chronic bronchitis (determined by questionnaire) and the anatomic criteria for the definition of emphysema (determined by radiologic or

pathologic studies). Airflow obstruction is more likely with greater severity of anatomic emphysema, but a substantial fraction of subjects with airflow obstruction do not have significant emphysema, and some subjects with significant emphysema do not have airflow obstruction (32,33). To date, it remains unclear what genetic, environmental, and pathobiological factors contribute to this less-than-perfect correlation.

### 60.3.4 Biochemical Markers

A variety of biochemical markers have been developed in an effort to reflect the inflammation and tissue destruction of COPD. The decline in pulmonary function tests, such as FEV<sub>1</sub>, in COPD is a gradual process. Therefore, detection of a change in the rate of decline in FEV<sub>1</sub> in response to treatment may require a long period of observation in a large number of subjects. If biochemical assays in readily obtainable samples (e.g. blood, urine) could be used as surrogate markers for the pathophysiological process leading to loss of pulmonary function in COPD, the efficacy of novel treatment approaches could be assessed more rapidly.

As lung elastin degradation appears to be critical for the development of emphysema, serum levels of elastin-derived peptides and urine levels of desmosine (a specific breakdown product of elastin) have been developed (34,35). As desmosine is exclusively excreted in the urine, urine measurements of desmosine levels have typically been performed (36). A radioimmunoassay for desmosine measurement was reported by King et al. in 1980 (36). Pelham et al. compared the desmosine levels in urine samples that had been hydrolyzed with hydrochloric acid to release desmosine from elastin in 17 severely AAT-deficient subjects (PI Z) with COPD and 27 healthy control subjects; no differences in urine desmosine levels were detected between these groups (37). Subsequently, Starcher and Scott demonstrated that urine contained several substances that interfered with the accurate measurement of desmosine levels by immunoassay; they developed purification procedures, including hydrolysis with acetone and extraction with chloroform/ethanol, to remove these contaminants (38). Stone et al. developed an alternative approach to remove urine contaminants; they developed a high-performance liquid chromatography (HPLC) assay for desmosine measurement that also measures isodesmosine (another specific elastin breakdown product) and hydroxylsypyrindoline and lysypyrindoline (specific collagen breakdown products) (39). Stone et al. subsequently compared urine desmosine levels using this HPLC assay in 22 lifelong nonsmokers, 13 current smokers without airflow obstruction, and 21 COPD patients (34). In univariate analysis, desmosine and isodesmosine levels in smokers with and without COPD were similar; both groups had elevated levels compared to nonsmokers. In multivariate analysis, COPD appeared to be associated with

increased desmosine and isodesmosine levels. Of interest, Stone et al. found elevated levels of the specific collagen breakdown products in COPD patients compared to either smokers without airflow obstruction or lifelong nonsmokers. More recently, Ma et al. have developed a more sensitive method for measuring desmosine and isodesmosine using HPLC followed by electrospray ionization mass spectroscopy; this method is able to detect the low amounts of free desmosine and isodesmosine in urine, and total desmosine and isodesmosine in sputum from COPD subjects (40).

Additional efforts to develop novel biochemical markers in COPD have focused on the assessment of inflammation and oxidative stress. For example, Montuschi et al. found elevated levels of 8-isoprostane, a potential biomarker of oxidative stress, in exhaled breath of COPD subjects compared to both smoking and nonsmoking control subjects (41). Subsequently, Biernacki et al. showed that 8-isoprostane levels in exhaled breath increase during COPD exacerbations (42).

However, despite the potential utility of a biomarker for elastin degradation or COPD-related inflammation, none of these various biochemical phenotypes has been consistently validated in large numbers of subjects. Moreover, they have not been applied as phenotypes in genetic studies of COPD.

Recently, several large-scale clinical studies have been conducted to identify novel biomarkers. One such study is Evaluation of COPD Longitudinally to Identify Predictive Surrogate End-points (ECLIPSE), a 3-year longitudinal study to define the parameters that characterize subgroups and predict disease progression in more than 2000 individuals with COPD (43). Lomas et al. evaluated 2083 individuals aged 40–75 years with COPD and a smoking history of  $\geq 10$  pack-years, 332 controls with a smoking history of  $\geq 10$  pack-years and normal lung function, and 237 nonsmoking controls in the ECLIPSE cohort. They demonstrated that serum clara cell (CC) protein-16 levels were reduced in individuals with COPD and that there is a weak correlation with disease severity in former smokers (44). Lomas et al. also demonstrated that serum surfactant protein D was significantly elevated in 1888 individuals with COPD compared to 296 current and former smokers without airflow obstruction and 201 nonsmokers although there was no correlation with the severity of COPD (45). In 488 COPD patients from the ECLIPSE cohort, Singh et al. demonstrated that sputum neutrophil levels are associated weakly with FEV<sub>1</sub> % predicted and health status (46). The value of sputum counts in COPD appears to be principally as a tool for measuring the burden of neutrophils in the airways although sputum counts do not appear to be a major surrogate biomarker in COPD.

Another study is SubPopulations and Intermediate Outcome Measures In COPD Study (SPIROMICS), which will follow several thousand patients with COPD

across six US sites and is sponsored by the National Institutes of Health ([www.csc.unc.edu/spir/](http://www.csc.unc.edu/spir/)).

More recently, the Genetic Epidemiology of COPD (COPDGene) study, which is a multicenter observational study, was designed to identify genetic factors associated with COPD and characterize chest CT phenotypes in subjects with COPD, including assessment of emphysema, gas trapping, and airway wall thickening. Subtypes of COPD based on these phenotypes will be used in a comprehensive genome-wide study to identify COPD-susceptibility genes. The COPDGene study will enroll 10,000 smokers with and without COPD across the Global Initiative for Chronic Obstructive Lung Disease (GOLD) stages. Two groups are studied: non-Hispanic whites and non-Hispanic African-Americans (47).

Budoff et al. demonstrated that correlations between gated and ungated coronary artery calcification and thoracic aortic calcification were excellent ( $r = 0.96$ ) in a study of 50 patients enrolled in the COPDGene study (48).

## 60.4 CIGARETTE SMOKING AND COPD

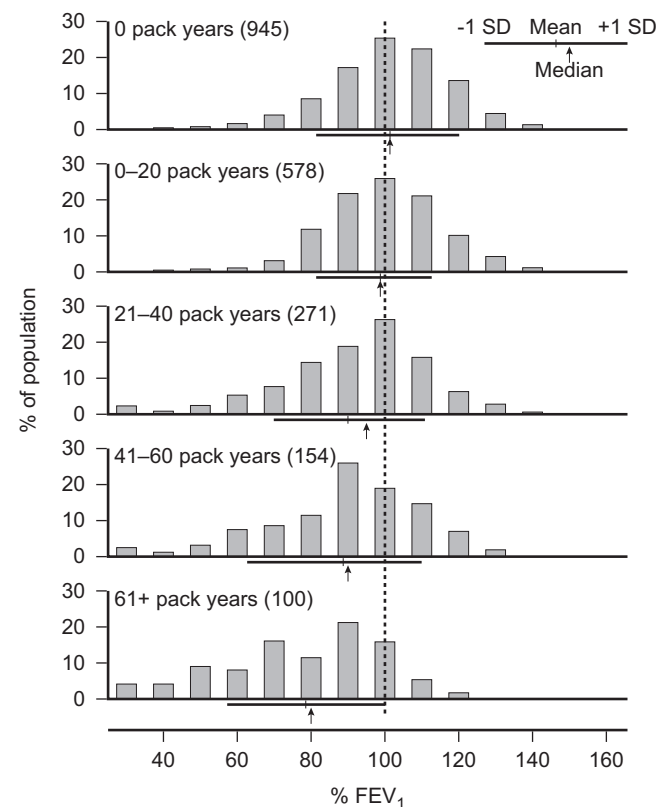

### 60.4.1 Causal but Variable Relationship of Smoking and COPD

In the 1950s, the most widely advanced hypothesis for the etiology of COPD was that progressive lung damage was caused by air pollution or recurrent respiratory infections. By 1964, adequate epidemiological evidence had accumulated for the Advisory Committee to the Surgeon General to conclude that “Cigarette smoking is the most important of the causes of chronic bronchitis in the United States, and increases the risk of dying from chronic bronchitis and emphysema” (page 31) (49). Ezzati et al. reported that the estimated fraction of COPD mortality attributable to smoking was 54% for men aged 30–69 years and 52% for men aged  $\geq 70$  years (50). Nearly all of the studies on which the 1964 Surgeon General recommendations were based were cross-sectional in design. Subsequent longitudinal studies have shown accelerated decline in FEV<sub>1</sub> in a dose-response relationship to cigarette smoking, related to both the duration of smoking and the amount smoked (51,52). This dose-response relationship of pulmonary function decline with cigarette smoking accounts for the observed higher prevalence rates for COPD with increasing age. The historically higher rate of smoking among males is the likely explanation for higher prevalence of COPD among males; however, the prevalence of COPD among females is increasing, in accordance with more recent increases in the rate of smoking among women (53).

It is well known that cigarette smoking is a major risk factor for the development of COPD. In 1977, Burrows et al. demonstrated a dose-response relationship between FEV<sub>1</sub> (percentage predicted) and pack-years of cigarette smoking in a study of 2369 individuals (51). The variable

relationship between FEV<sub>1</sub> and cigarette smoking intensity in the Burrows study is demonstrated in Figure 60-4. Heavier smokers were more likely to develop airflow obstruction, indicated by reduced FEV<sub>1</sub>. However, many smokers had pulmonary function within the normal range. In the Burrows study, pack-years, defined as the average number of packs of cigarettes smoked per day multiplied by the number of years of smoking, was the smoking-related variable that correlated most closely with FEV<sub>1</sub>. However, pack-years of smoking only accounted for about 15% of the variability in FEV<sub>1</sub>.

Pathologic studies of emphysema have demonstrated variability in the development of emphysema as well. Auerbach et al. performed an autopsy study of smokers; many smokers had pathologic evidence for emphysema, but the extent of emphysema varied widely (54). In another early autopsy study, Petty et al. also demonstrated marked variability in the development of emphysema among smokers (55). More recently, a study of lung pathology in smokers demonstrated that microscopic emphysema, assessed by quantitative measurements of airspace wall surface area per unit volume of lung tissue, was present in only 26% of smokers (56). On the basis of these pathologic studies, variability in the development

**FIGURE 60-4** Distributions of FEV<sub>1</sub> (% predicted) values with varying pack-year histories of smoking among adult subjects in the study by Burrows et al. Mean, median, and  $\pm 1$  standard deviation for FEV<sub>1</sub> are shown for each group. A dose-response relationship between increased smoking intensity and reduced FEV<sub>1</sub> is present, but many heavy cigarette smokers have FEV<sub>1</sub> values within the normal range. (From Burrows et al., 1977 (51).)

of emphysema in response to cigarette smoking is clearly present. However, it remains unclear if only a minority of smokers develops COPD (the susceptible smokers) or if all smokers develop some pathologic changes of COPD, but only a minority develops severe disease.

In part, the variable relationship between cigarette smoking and COPD relates to competing risks; cigarette smokers may die from other smoking-related illnesses such as coronary artery disease or lung cancer before the development of COPD. However, as discussed, genetic factors likely also influence the variable susceptibility to develop COPD. Because cigarette smoking is a proven major environmental risk factor for COPD, which can be readily assessed with questionnaires, COPD offers unique opportunities and challenges to incorporate environmental influences in the study of genetics of complex diseases. Genetic determinants of COPD may influence the development of COPD through a genotype-by-environment interaction between cigarette smoking and susceptibility genes. According to an official American Thoracic Society public policy statement on novel risk factors and the global burden of COPD in 2010, population-attributable fraction for smoking as a cause of COPD ranged from 9.7% to 97.9% but was <80% in most studies, indicating a substantial burden of disease attributable to nonsmoking risk factors (57).

### 60.4.2 Effects of Smoking at Different Life Stages

The effects of cigarette smoking, and potentially other environmental influences, on pulmonary function likely depend on the intensity of the environmental exposure, the timing of the exposure during growth, and the baseline lung function of the individual. Cunningham et al. estimated that maternal smoking during pregnancy resulted in a 1.3% reduction in FEV<sub>1</sub> when exposed children reach the ages of 8–12 years (58). Tager et al. examined the effect of actively smoking cigarettes during adolescence; individuals who smoked cigarettes from age 15 through age 20 were estimated to have an 8% reduction in FEV<sub>1</sub> (59). Xu et al., with data from the Vlagtwedde/Vlaardingen Study in The Netherlands, demonstrated that there was a large effect of cigarette smoking to decrease maximal level of lung function in individuals age <20 that far exceeded the effect of cigarette smoking on decline in lung function in older age groups (60). Therefore, dose and timing of exposure to cigarette smoke can have a profound impact on disease expression at different stages of the life cycle. Indeed, exposure to cigarette smoking in utero or active smoking in adolescence may have far greater effects on pulmonary function many years later than active smoking after the age of 35.

Cigarette smoking is the major environmental risk factor for the development of COPD. A variety of other potential environmental risk factors also have been

suggested although the supporting data are much less compelling; these potential risk factors include respiratory infections, occupational exposures, ambient air pollution, passive smoke exposure, and diet (61).

## 60.5 SEVERE AAT DEFICIENCY

A small percentage of COPD patients (estimated at 1–2%) inherit severe AAT deficiency (62). We discuss AAT deficiency in some detail because it is a proven genetic risk factor for COPD, and because it can serve as a model of the manner, in which genetic and environmental factors can interact to lead to COPD.

### 60.5.1 Description of the Protease Inhibitor Locus and Protease Inhibitor Alleles

AAT is encoded by the protease inhibitor (PI) locus (Human Genome Organisation name SERPINA1) on chromosome 14q32.1 (63,64). The PI gene, which is 12.2kb in length, has seven exons and six introns; the structure of the PI locus is shown in Figure 60-5. The first two exons and a short sequence of the third exon are encoded in the transcript produced by macrophages, but not by hepatocytes. Most of the fourth exon, and all of the remaining three exons, encode the protein sequence. The active inhibitor site P1 amino acid residue, methionine 358, is encoded by exon V. A “sequence-related gene,” which is likely a pseudogene, is found 12kb downstream from the PI locus (65).

The dominant site of synthesis of AAT is the liver but AAT is also synthesized in monocytes, macrophages, and neutrophils (66,67). AAT is a 394-amino acid protein (52 kDa); salt bridges within the molecule include glutamic acid 342 to lysine 298 and glutamic acid 264 to lysine 387.

The discovery of AAT deficiency was made by observing the absence of an alpha 1-globulin band in serum protein electrophoresis (6). Subsequently, differences in electrophoretic mobility of various AAT forms, related to differences in molecular surface charge, were demonstrated (68). The most common variant was designated M for medium rate of migration. Variants that migrated faster and slower than M were called F and S, for faster and slower migration, respectively. The Z form of the protein migrated much slower than the S form.

Approximately 100 different PI alleles have been identified, a few of which result in decreased serum levels of AAT (69). A partial list of PI variants is provided in Table 60-1. The common M allele, with an allele frequency >95% in US populations, is associated with normal AAT levels. The S allele, which is associated with slightly reduced AAT levels, and the Z allele, which is associated with markedly reduced AAT levels, also occur in US populations. A small percentage of subjects inherit null alleles, which lead to the absence of any AAT

**FIGURE 60-5** Structure of PI locus. The gene includes seven exons (IA, IB, IC, II, III, IV, and V); the coding sequence is contained in exons II to V. A signal peptide is encoded by exon II, following the translation start site (ATG) for the AAT mRNA. Hepatocyte transcription begins within exon IC and is controlled by the region denoted by the solid line. Transcription in monocytes and macrophages begins with exon IA. The three carbohydrate attachment sites are noted at amino acid residues 46, 83, and 247. The site of the critical active site methionine (amino acid residue 358) is also indicated. (From Brantly et al., 1988 (70).)

**TABLE 60-1** Structure of Representative Allelic Variants at the PI Locus

		Amino Acid Residue Change			
PI Allele	Type of Mutation	AA#	From	To	Cellular Defect
Normal alleles					
M1 (Ala213 or Val213)	Substitution (1 bp)	213	ala	val	None
M2	Substitution (1 bp)	101	arg	his	None
M2	Substitution (1 bp)	376	glu	asp	None
M3	Substitution (1 bp)	376	glu	asp	None
F	Substitution (1 bp)	223	arg	cys	None
Xchristchurch	Substitution (1 bp)	363	glu	lys	None
Deficient alleles					
S	Substitution (1 bp)	264	glu	val	IC degradation
Z	Substitution (1 bp)	342	glu	lys	IC accumulation
Mmalton	Deletion (3 bp)	52	phe	none	IC accumulation
Siiyama	Substitution (1 bp)	53	ser	phe	IC accumulation
Mheerlen	Substitution (1 bp)	369	pro	leu	IC degradation
Mprocida	Substitution (1 bp)	41	leu	pro	IC degradation
Null (QO) alleles					
QOgranite falls	Deletion (1 bp)	160	tyr	stop	Stop at 160—no mRNA
QOludwigshafen	Substitution (1 bp)	92	ile	asn	No protein
QOclayton	Insertion (1 bp)	363	glu	arg	Stop at 376; IC degradation
QOhongkong	Deletion (2 bp)	318	leu	leu	Stop at 334; IC accumulation
QOisola di procida	Deletion (17 kbp)				No mRNA
Dysfunctional Alleles					
Pittsburgh	Substitution (1 bp)	358	met	arg	Antithrombin 3 activity

IC corresponds to intracellular.

Only a partial list of PI alleles is presented; see Huber and Carrell (Huber and Carrell 1989) and Brantly et al. (Brantly et al. 1988a) for more details.

production through a heterogeneous collection of mutations (see below) (70). Individuals with two Z alleles or one Z and one null allele are referred to as PI Z because they cannot be distinguished by the isoelectric focusing technique commonly used to assess PI type. PI Z individuals have approximately 15% of normal plasma antitrypsin levels.

Additional improvements of isoelectric focusing techniques led to the discovery of variants within the class

of PI\*M alleles (71,72). The M subtypes are designated numerically as M1, M2, M3, and so on. The M subtypes, which are all associated with normal AAT serum levels, follow the codominant inheritance pattern for protein expression of other PI alleles.

The PI locus was initially designated as Pi; however, the International System for Human Gene Nomenclature proposed using only capital letters for locus designation, with the symbol PI for the PI locus (73). Although both

Pi and PI are still used to designate the PI locus, we have chosen to use PI in this chapter.

An international committee's recommendations for nomenclature at the PI locus, developed at a meeting in 1978, included designation of alleles with capital letters based on their relative positions by isoelectric focusing of serum (74). Alleles may be designated as superscripts or following an asterisk; for example, the S allele was PI<sup>S</sup> or PI\*S. If no unused letter is available, a number is added to the nearest lettered allele (e.g. M2, M3) or the place of origin of the first person identified with the allele is included adjacent to the letter (e.g. Mheerlen). Phenotypes from PI typing are designated as PI M, PI Z, and so on. Phenotypes from PI typing are designated with a single letter to represent data from electrophoresis results, such as PI M; however, if family data or M allele subtypes (e.g. M1 and M2) support the presence of, for example, 2 PI\*M alleles in an individual, the designation PI MM is appropriate. In practice, the applied nomenclature has varied widely, and superscripts, asterisks, and other terms are used inconsistently to designate specific alleles.

Null alleles (also referred to as QO alleles) lead to the absence of AAT protein production through a variety of mechanisms. Single base substitutions, insertions, and deletions resulting in a premature stop codon have been reported; the consequences of premature termination of mRNA synthesis include the absence of mRNA production (as seen in QOgranite falls), intracellular accumulation of a truncated protein (as seen in QOhongkong), and intracellular degradation of a truncated protein (as seen in QOclayton) (75–77). Mechanisms other than premature stop codon formation that have resulted in null alleles include gene deletion (PI\*QOisola di procida) and critical amino acid substitutions (PI\*QOludwigshafen) (78,79). Brantly et al. noted that several different null alleles have been described that result from mutations in a series of seven cytosine nucleotides from codons 360 to 362 (77).

Differences in nomenclature of null alleles persist; some investigators have used PI\*QO followed by the birthplace of the subject; others have used the term “null” followed by the birthplace of the individual. A few null–null individuals have been identified, who have no detectable serum AAT (80); for example, Garver et al. presented a 35-year-old nonsmoker with severe COPD who was null–null, and Cox and Levison described three null–null siblings with COPD (81,82). Null–null individuals seem to have an extremely high predisposition to develop COPD but the number of subjects that have been identified is too small to quantitate the risk relative to PI Z individuals with certainty (82).

In addition to null alleles, a variety of very rare PI alleles with electrophoretic mobility similar to the M protein have been described, which are associated with very low serum levels of AAT. Some of these rare variants, such as Mheerlen and Mprocida, are associated with reduced AAT levels because of intracellular degradation

of AAT; other rare variants, such as Mmalton, Mni-chinan, and Siiyama, are associated with reduced AAT levels because of intracellular accumulation of protein (Table 60-1). An extremely rare PI variant, antitrypsin Pittsburgh, involved a substitution of arginine for methionine at the critical P1 active site residue (83). This variant inhibited thrombin instead of leukocyte elastase, and acute-phase responses resulted in elevated levels of antithrombin activity, which led to severe hemorrhagic complications.

### 60.5.2 Diagnosis of AAT Deficiency

The clinical laboratory test used most frequently to screen for AAT deficiency is measurement of the immunological level of AAT in serum. The definitive diagnosis of AAT deficiency requires PI type determination, but measurement of serum immunological or functional levels can be used for screening, as long as appropriate methods to quantitate AAT levels are used. Available assays for measurement of immunological AAT levels include immunoelectrophoresis (rocket test), turbidometric assays, enzyme-linked immunoassays, and radial immunodiffusion plates. Methods that are based on quantitation of the alpha 1-globulin peak (which is largely AAT) from serum protein electrophoresis (SPEP) are unreliable, because the large albumin peak in SPEP analysis could provide falsely elevated estimates of alpha 1 globulin levels.

Problems with commercial standards used to measure serum levels of AAT have led to overestimation of measured levels by up to 40% (84). To avoid confusion with commercial laboratory measurements, which are typically reported in units of milligrams per deciliter, investigators using purified laboratory standards have typically reported AAT concentrations in units of micromolar values.

Isoelectric focusing of serum in polyacrylamide gels in the pH range of 4.0–5.0 remains the most common method for the determination of PI type. AAT is a negatively charged glycoprotein that resolves into eight bands when subjected to electrophoresis near its isoelectric point. Isoelectric focusing of serum can accurately determine PI type, which reflects the genotype at the PI locus for the common alleles. Molecular genotyping can distinguish the common PI alleles (M, S, and Z) using restriction fragment length polymorphism-based assays, oligonucleotide hybridization, or a variety of other molecular genotyping approaches, using blood, dried blood spots, or buccal brushings (85,86). However, high-throughput molecular genetic tests for rare deficiency alleles are not widely available, so rare severe deficiency alleles (e.g. null alleles) can be misclassified as normal if only these molecular genetic approaches are used. Thus, additional testing, such as measurement of serum AAT level, is required in addition to molecular genotyping of the common alleles in order to exclude rare deficiency states.

The PI locus demonstrates autosomal codominant expression of protein variants because individuals with, for example, PI MZ will produce both M and Z proteins. However, the development of COPD and liver disease are expressed in an autosomal-recessive mode because two deficiency alleles are required to cause a significant increase in risk for these diseases (see discussion of controversy regarding the risk for Z allele heterozygotes below).

The genotype at the PI locus is the primary genetic determinant of the serum AAT level. AAT is an acute-phase reactant protein that increases in the bloodstream with systemic infection or other stresses; therefore, environmental factors can influence AAT serum levels. Martin et al. studied immunological and functional levels of serum AAT in 583 individuals from 114 pedigrees (87). They noted that the PI locus appeared to be the only important genetic determinant of serum AAT level because adding polygenic determinants to quantitative genetic models that included PI type effects did not improve the fit of their models. Using measured genotype analysis, Silverman et al. estimated that depending on adjustment for covariates, PI type explained between 72% and 92% of variation in immunological serum AAT levels within families of PI Z subjects (88). Thus, most, if not all, of the genetic variation in serum AAT level appears to be controlled by the PI locus.

### 60.5.3 Pathogenesis of COPD in Severe AAT Deficiency

AAT is a member of the serpin family of PIs, which are involved in the modulation of serine proteases—a group of enzymes that trigger such important inflammatory cascades as the activation of complement, coagulation, kinin release, and fibrinolysis. The critical P1 amino acid residue at the active inhibitor site differs between members of the serpin family and tends to dictate specificity of the inhibitor. Typically, enzyme inhibition with the serpins involves proteolytic cleavage during formation of the complex with enzyme and permanent inactivation of the enzyme.

AAT is the major plasma PI of leukocyte elastase (encoded by the *ELA2* gene)—one of the enzymes that has been hypothesized to play a role in the development of emphysema (89). AAT also demonstrates protease inhibitor activity against proteinase 3, cathepsin G, chymotrypsin, trypsin, plasmin, and thrombin, but the highest rate constant of association is for leukocyte elastase (90). Functionally, the most important residue of AAT is methionine at position 358, the P1 residue at the active inhibitory site. This active site has been localized to a tensely strained loop of 16 amino acid residues that protrudes from one end of the molecule in a pattern that provides an attractive bait for the active site of leukocyte elastase (91). Inhibition of leukocyte elastase involves hydrolysis of the 358–359 bond between methionine and

serine; after hydrolysis, elastase remains bound to the antitrypsin molecule, preventing further enzyme activity.

The Z allele encodes a single base substitution that replaces glutamic acid at amino acid position 342 with lysine; this substitution eliminates a salt bridge that is usually present between amino acid residue 342 and the lysine at amino acid residue 290. PI Z individuals have approximately 15% of normal plasma antitrypsin levels because the Z protein polymerizes within the endoplasmic reticulum of hepatocytes (92). Although the Z form of the AAT protein is somewhat less functional as a PI than the M form on a molecule-by-molecule basis (93), the primary mechanism for reduced AAT activity in PI Z individuals is the reduced serum level of the Z protein in PI Z individuals.

The molecular mechanism for reduced secretion of Z AAT has been deduced by Mahadeva et al. (92,94). The Z protein accumulates in hepatocytes in globules within the endoplasmic reticulum that are strongly stained by periodic acid-Schiff stain after diastase treatment. The formation of these aggregates of Z protein results directly from the point mutation at amino acid residue 342, which is located at the base of the reactive center loop of the AAT molecule. The reactive center loop of one M antitrypsin molecule can move in and out of the A beta-sheet in an adjacent M antitrypsin molecule; with elevated temperatures (41°), the M protein forms polymers of AAT molecules. However, the mutation in the Z allele enhances the tendency toward this loop-sheet polymerization, which occurs spontaneously at 37° with the Z protein (94). The structure of the AAT protein and a model of loop-sheet polymerization are shown in Figure 60-6. Lomas et al. also demonstrated that loop-sheet polymerization was found with the two other PI variants that result in intracellular accumulation of AAT, Siyama and Mmalton (95,96). Extracellular polymerization of AAT Z molecules has been demonstrated, which represents an additional mechanism that reduces the antiprotease activity in PI Z subjects (97). Of interest, these extracellular antitrypsin polymers are chemotactic for neutrophils, which may contribute to increased inflammation and lung parenchymal destruction in PI Z subjects (98).

About 90% of the elastase inhibitor activity in the lower respiratory tract is provided by AAT; the remainder is due to secretory leukoprotease inhibitor, elafin, and alpha 2-macroglobulin (99,100). Lung epithelial lining fluid from cigarette smokers contains normal levels of AAT measured immunologically but sharply decreased levels of elastase inhibitory activity (101). The methionine 358 P1 active site residue of AAT may be oxidized and inactivated by exposure to cigarette smoke or to oxidative bursts from inflammatory cells (102,103). Oxidative inactivation has been proposed as a potential mechanism for the pathogenesis of emphysema in cigarette smokers with normal PI types, by creating a functionally antitrypsin deficient state (104). AAT

**FIGURE 60-6** Structure of the AAT molecule and model for loop-sheet polymerization. (A) Ribbon diagram of AAT molecule with a cleaved reactive center loop (in black), which is inserted into the A beta-sheet of the AAT molecule. Beta-pleated sheets and alpha-helices are shown in gray. (B) The active inhibitory molecule of AAT includes a reactive center loop which is exposed for binding with proteinase. (C) Adjacent molecules of active AAT can polymerize by insertion of the reactive center loop of one molecule into the A beta-sheet of an adjacent molecule. Extended polymer formation results in hepatocyte globule formation in PI Z subjects. (From Elliott et al., 1996 (247).)

in the lung lining fluid can be inactivated by oxidation, complex formation with elastase, or fragmentation; the relative importance of these mechanisms of inactivation remains uncertain.

The recognition of an association between heritable AAT deficiency and pulmonary emphysema was a central event in the development of the protease–antiprotease hypothesis for the pathogenesis of emphysema. This hypothesis generally states that when proteolytic enzymes (especially leukocyte elastase) are released into the lungs, PIs normally prevent lung tissue destruction. The PI in highest concentration and with the highest association constant for leukocyte elastase is AAT (89). When PI levels are too low relative to protease levels, the uninhibited proteases cause lung destruction—elastin degradation is apparently critical—which eventually leads to emphysema (105,106).

The requirement for contact between inflammatory cell and extracellular matrix substrate raises important issues regarding the biochemical microenvironment in the lung interstitium. Campbell pointed out that proteolytic

events may be spatially controlled in the extracellular matrix at or near the cell membrane (107). This has been demonstrated by addition of neutrophils to a fibronectin-coated plate in the presence of excess AAT. Degradation of fibronectin occurs only where the cells contact the plate in such a manner as to exclude the PI. Thus, selected areas of the microenvironment have enzyme-inhibitor balance that differs from the whole lung. Campbell et al. have also demonstrated that proteolytic damage related to individual azurophil granules of neutrophils could be detected. The diameter of the region of extracellular matrix destruction from individual azurophil granules was substantially larger when serum from PI Z subjects was used than when serum from PI M subjects was used to provide the antiproteases (108).

#### 60.5.4 Prevalence of Severe AAT Deficiency

The prevalence of AAT deficiency is especially elevated in populations of Scandinavian descent. Analysis of the haplotypes of polymorphic loci adjacent to the AAT Z allele suggests that there was likely a common mutational origin for the majority of Z alleles, which may have occurred in northern Europe (109).

A variety of screening studies for AAT deficiency have been performed. Because of the rarity of severe AAT deficiency (e.g. PI ZZ), the prevalence of severe AAT deficiency is often estimated from the Z allele frequency, using Hardy–Weinberg equilibrium assumptions. Hutchison reviewed the European studies that estimated Z allele frequency and noted that the highest Z allele frequencies were found in the north-western section of Europe (including southern Sweden, Norway, Denmark, and the United Kingdom) (110). Prevalence surveys have typically found low Z allele frequencies in populations of African and Asian descent (111). de Serres performed a comprehensive search of S and Z allele frequency estimates in previously published control cohorts from around the world (112). He noted that there may be substantial numbers of PI ZZ subjects in almost every region of the world, including Asia and Africa. de Serres et al. later reported striking differences in the prevalences of both the PIS and PIZ alleles among these 69 countries and the numbers at risk for AAT deficiency in a given country in specific geographic regions (113). Data on the prevalence of the PIS and PIZ alleles as well as the numbers in those phenotypic classes known to be at risk for AAT deficiency are considered critical for the identification of individuals at risk for adverse health effects associated with AAT deficiency, as well as the treatment and management of those individuals identified in a given country. In the United States, de Serres et al. reported that the highest risk for AAT deficiency is found in whites, followed by Hispanics and blacks, with the lowest prevalence among Mexican Americans and no risk among Asians (114).

An alternative approach to estimate the prevalence of severe AAT deficiency involves direct screening for severely deficient individuals. The largest screening study was a survey of 200,000 newborns in Sweden from 1972 to 1974; a prevalence estimate of 1 in 1639 for PI Z individuals was determined from this screening effort (115). A large newborn screening program in Oregon identified 21 PI Z infants in a population of 107,038, for a prevalence estimate of 1 in 5097 (116). However, confirmation of PI Z in the Oregon study required a follow-up test, so some PI Z infants may have been missed, resulting in an underestimate of PI Z prevalence. In a population of 20,000 blood donors in the United States, Silverman et al. found seven PI Z subjects, for a prevalence of approximately 1 in 2667 (117). Pooled data from 26 other screening studies of populations, which included Z alleles (excluding Sweden and the United States) revealed a prevalence of eight PI Z subjects in 19,768 individuals screened (1 in 2471) (117). Thus, although the highest prevalence rates of PI Z subjects has been noted in Sweden, the differences between the prevalence of PI Z subjects in Sweden compared to other Caucasian populations may not be as great as previously assumed.

### 60.5.5 Natural History of PI Z

PI Z individuals often have early-onset COPD. Among PI Z subjects with COPD, panacinar emphysema with predominant involvement of the lung bases has been classically described. However, recent data based on chest CT scans indicate that PI Z subjects with COPD frequently have diffuse emphysema, without a basilar predominance, or even upper lobe predominant emphysema (118).

Only three of the first five PI Z patients had clinical manifestations of airflow limitation (6); thus, variability in the development of pulmonary complications was evident from the initial description of severe AAT deficiency. Published series of PI Z individuals have usually included many PI Z subjects with COPD; however, these studies have largely included PI Z individuals who were tested for AAT deficiency because they already had COPD (119–122). Thus, the fraction of PI Z individuals who will develop COPD and the age-of-onset distribution for the development of COPD in PI Z subjects remain unknown. PI Z subjects are also at increased risk for liver diseases, including hepatic cirrhosis; however, discussion of liver disease is beyond the scope of this chapter.

Several large series of AAT-deficient individuals reported in the 1970s and 1980s clearly demonstrated that PI Z subjects who smoke cigarettes tend to develop more severe pulmonary impairment at an earlier age than nonsmoking PI Z individuals (119–121). Larsson estimated survival probabilities in PI Z subjects using a life table approach (120). He estimated that the median

survival of PI Z smokers would be 23 years less than PI Z nonsmokers. Subsequently, Seersholm et al. confirmed the markedly different mortality rates in PI Z smokers and nonsmokers using the Danish Alpha 1-antitrypsin Register; lifelong nonsmokers had similar mortality rates to the general Danish population (123).

Few studies have considered whether factors other than smoking influence the development of lung disease in PI Z subjects. Black and Kueppers studied 18 nonsmoking PI Z individuals and 36 PI Z subjects who were current or exsmokers (124). They found significant variability in pulmonary function and clinical symptoms, especially among nonsmoking PI Z individuals. For instance, nine of 18 nonsmoking PI Z subjects had a chronic cough, while 33 of 36 smoking PI Z subjects reported a chronic cough. Pulmonary function tests, which included FEF<sub>25–75</sub> and diffusing capacity, were widely variable among the nonsmokers and did not decrease systematically with increasing age. They speculated that unidentified host factors contribute to this variability.

Identification of many PI Z subjects, because they already have COPD, has influenced perceptions about the natural history of this disorder. In a study performed in St. Louis, Silverman et al. included 52 PI Z subjects, ascertained as noted below (125); significant variability in pulmonary function was found (Figure 60-7). In Figure 60-7, index PI Z subjects, who were tested for AAT deficiency because they had COPD and who were the first PI Z identified in their family, all had significantly reduced FEV<sub>1</sub> values. Non-index PI Z subjects, who were ascertained by a variety of other means, including family studies, population screening, and liver disease, suggest a much different natural history for severe AAT deficiency than index PI Z subjects. Many non-index PI Z subjects have preserved pulmonary function. With subjects identified from the Danish Alpha 1-antitrypsin Register, Seersholm et al. also found significantly higher FEV<sub>1</sub> values in non-index PI Z subjects (not identified because they had COPD) compared to index PI Z subjects (identified because they had COPD) despite similar ages and smoking histories (126).

Piitulainen et al. assessed environmental determinants of reduced lung function other than cigarette smoking in a group of 205 lifelong nonsmoking PI Z subjects in Sweden. They found no relationship between reported passive smoke exposure and reduced FEV<sub>1</sub>; however, use of a kerosene heater and working in an agricultural occupation were significantly associated with reduced lung function (127). In a series of 128 PI Z individuals, Mayer et al. found that high mineral dust exposure was associated with increased cough and reduced FEV<sub>1</sub> values (128).

The natural history of PI Z subjects in the general population remains uncertain. There are likely three groups of unidentified PI Z subjects in the general population: (1) PI Z subjects with diagnosed COPD who have

**FIGURE 60-7** Effect of ascertainment bias on percent predicted FEV<sub>1</sub> among 52 severely AAT deficient subjects (PI Z) in the study by Silverman et al. Closed circles represent index PI Z subjects (individuals diagnosed with severe AAT deficiency because they had COPD, and who were the first PI Z subject identified in their family); open symbols represent non-index subjects. Nonindex subjects were ascertained by liver disease (open circles), family studies (squares), population screening (triangles), and other pulmonary problems (stars). Marked variability in FEV<sub>1</sub> values is evident for the non-index PI Z subjects. (From Silverman et al., 1989 (125).)

not been tested for AAT deficiency (possibly because they were not diagnosed with early-onset COPD); (2) PI Z subjects with significant but unrecognized airflow obstruction who have not been diagnosed with COPD (and thus AAT deficiency was not considered); and (3) PI Z subjects with normal pulmonary function. However, the relative proportions of these groups are unknown.

### 60.5.6 Other Familial Factors Influencing the Expression of AAT Deficiency

The primary focus of the St. Louis AAT study was to determine if genetic factors other than PI type influenced the variable development of lung disease among PI Z subjects. Therefore, first-degree relatives of the 52 PI Z subjects were enrolled. Despite comparable smoking histories, parents of PI Z subjects with reduced FEV<sub>1</sub> tended to have lower FEV<sub>1</sub> values themselves compared to parents of PI Z subjects with preserved FEV<sub>1</sub> (129). Elevated total serum immunoglobulin E levels in relatives of COPD PI Z subjects compared to relatives of healthy PI Z subjects suggested a relationship between familial factors influencing reduced pulmonary function and atopy. These results, as well as the findings with segregation analysis from the St. Louis study discussed below, suggested that additional genetic factors influence the development of airflow obstruction in AAT deficiency. Moreover, Silverman et al. demonstrated that significant genotype-by-environment interaction between PI type and pack-years of smoking was present (88).

Novoradovsky et al. assessed whether variation in the endothelial nitric oxide synthase gene (NOS3) could be one of the genetic factors that influences the variable development of airflow obstruction in PI Z subjects (130). They identified polymorphisms in the NOS3 gene, and they tested for genetic association of these variants with airflow obstruction in 55 PI Z subjects with FEV<sub>1</sub> < 35% predicted, 122 PI Z subjects with FEV<sub>1</sub> > 35% predicted,

and 93 control subjects. Two polymorphisms in the coding region, which likely do not lead to functionally important changes in the NOS3 protein, were associated with severe airflow obstruction in PI Z subjects. Further work to replicate this finding and to identify a functionally important variant will be required, but NOS3 is an intriguing possible contributor to the variable development of airflow obstruction in PI Z subjects.

### 60.5.7 Treatment of Severe AAT Deficiency

The most important therapeutic measure for subjects with severe AAT deficiency who smoke cigarettes or other tobacco products is smoking cessation. In addition to conventional treatment for COPD (smoking cessation, influenza/pneumococcal vaccinations, bronchodilator treatment, pulmonary rehabilitation, etc.), specific treatment for AAT deficiency in the form of intravenous augmentation therapy has been developed.

Research at the Pulmonary Branch of the NHLBI demonstrated that commercial scale enrichment for AAT from human plasma (Cohn Fraction IV) could be performed, and that intravenous augmentation therapy with this partially purified preparation was feasible and safe. Heat treatment at 60° for 10 h was shown to reduce the likelihood of transmission of viral pathogens (131). Wewers et al. reported results from a feasibility study of AAT augmentation therapy in 21 PI Z patients with COPD (100). These PI Z patients received weekly intravenous infusions of 60 mg/kg of functionally active AAT for 6 months. The stated goal was to achieve AAT levels in the bloodstream and lung that were greater than levels in PI SZ subjects (approximately 11 μM), because those subjects appear to be near the threshold level for increased COPD risk. As shown in Figure 60-8, serum AAT levels were maintained above the 11 μM threshold with weekly infusions of partially purified antitrypsin.

**FIGURE 60-8** Serum levels of alpha 1-antitrypsin measured by radial immunodiffusion in five patients with severe alpha 1-antitrypsin deficiency who received weekly intravenous alpha 1-antitrypsin augmentation therapy of 60 mg/kg. Serum alpha 1-antitrypsin levels are expressed relative to a commercial standard (mg/dL on left vertical axis) and relative to a laboratory standard ( $\mu\text{M}$  on right vertical axis). Each patient is denoted by a different symbol (e.g. open circle, open triangle); values were measured 30 min, 2 days, 4 days, and 7 days after each infusion. The target threshold level is indicated by a dashed line. (From Wewers et al., 1987 (100).)

Bronchoalveolar lavage was performed periodically in the subjects who were receiving augmentation therapy in the trial by Wewers et al.; significant increases in AAT levels in the lung epithelial lining fluid were demonstrated (100). Although there is considerable experience with weekly AAT infusions, monthly infusions also provide AAT levels above  $11 \mu\text{M}$  ( $80 \text{ mg/dL}$ ) for the majority of the following months (132). The therapeutic impact of AAT levels that fall below the  $11 \mu\text{M}$  threshold before the subsequent monthly infusion is unknown.

Since 1988, purified AAT has been marketed in the United States for the intravenous treatment of severe AAT deficiency; four commercial products are currently available (Prolastin-C, Aralast NP, Zemaira, and Glassia). The only FDA-approved treatment regimen is a weekly infusion of 60 mg/kg. A once-monthly infusion of larger amounts has also been shown to be safe and to have nearly equivalent biochemical effectiveness (132). Despite efforts to inactivate viruses in these products and the absence of reported cases of viral infection as a result of augmentation therapy, hepatitis B vaccination is recommended before starting augmentation therapy. Intravenous augmentation therapy (initially, Prolastin-C) was released by the FDA after biochemical efficacy had been demonstrated; intravenous AAT treatment resulted in increased AAT levels in serum and bronchoalveolar lavage fluid with increased antielastase activity. However, a randomized controlled trial of AAT replacement therapy was not performed at that time. Instead, a registry of AAT-deficient subjects was created in order to follow the natural history of AAT-deficient subjects with and without augmentation therapy (133). By 1992, 1129 severely AAT-deficient subjects, defined as serum AAT

level below  $11 \mu\text{M}$ , were enrolled in the NHLBI Registry (134). During 4 years of observation, 67% of registry participants were receiving augmentation therapy for at least part of the study. Among all subjects in the registry, receiving augmentation therapy was not associated with a significant difference in the rate of decline in  $\text{FEV}_1$ ; however, among subjects with  $\text{FEV}_1$  values in the range of 35–49% of predicted, augmentation therapy was associated with a slower rate of  $\text{FEV}_1$  decline ( $P = 0.03$ ). Because it was not a randomized controlled trial, differences in mortality and  $\text{FEV}_1$  decline in subjects receiving augmentation therapy could be influenced by selection bias. However, the NHLBI Registry data suggested that a subset of severely AAT-deficient subjects may benefit from augmentation therapy. An observational study comparing 198 exsmoking German PI Z subjects receiving weekly AAT augmentation therapy with 97 exsmoking Danish PI Z subjects who did not receive this treatment found similar results; a slower rate of  $\text{FEV}_1$  decline was observed in subjects with baseline  $\text{FEV}_1$  values between 31% and 65% predicted (135).

Development of a randomized controlled trial of augmentation therapy was not performed before FDA approval of Prolastin-C in the United States, because the estimated sample size required to demonstrating a change in the rate of decline in  $\text{FEV}_1$  was judged to be impractical (136). Investigators in Denmark and The Netherlands reported a randomized controlled trial of augmentation therapy in 56 PI Z subjects with  $\text{FEV}_1$  values between 30% and 80% of predicted (137). Subjects received monthly infusions of AAT for 3–5 years; in addition to pulmonary function measurement every 3 months at the hospital, patients measured spirometry at

home on a daily basis. Annual chest CT scans also were performed. No significant differences in FEV<sub>1</sub> decline were noted in this relatively small study population; however, a trend toward reduction in longitudinal decline of chest CT density was noted in subjects receiving augmentation therapy ( $P = 0.07$ ). Therefore, chest CT scans may provide more sensitive phenotypes to detect beneficial effects of augmentation therapy in future studies.

More recently, the EXAcacerbations and CT scan as Lung Endpoints (EXACTLE) study (77 patients studied over 24–30 months), using a similar placebo-controlled trial design of intravenous AAT, explored CT densitometry as the primary outcome (NCT00263887) (138). CT densitometry showed a trend toward treatment benefit although the exacerbation frequency was not affected. This confirmed similar results from an earlier trial (137). Because of the similar study design and method of CT densitometry, Stockley et al. combined the raw data from these two studies (137,138) to increase the statistical power. The overall results of the combined analysis of two separate trials of comparable design, and the only two controlled clinical trials completed to date, have confirmed that intravenous AAT augmentation therapy significantly reduces the decline in lung density and may therefore reduce the future risk of mortality in patients with AAT deficiency-related emphysema (139).

A meta-analysis of randomized and nonrandomized studies included 1509 patients and found, however, that augmentation had a modest effect in slowing lung function decline in patients with AAT deficiency, and that patients with moderate obstruction are most likely to benefit (140).

Currently, eligibility for AAT augmentation therapy requires the demonstration of severe AAT deficiency, with a serum AAT level below 11  $\mu\text{M}$ . Augmentation therapy is not indicated for use in individuals with normal AAT levels or with deficient phenotypes associated with a level above 11  $\mu\text{M}$ . Typically, PI Z individuals will qualify although other rare types associated with severe deficiency (e.g. null-null) are also eligible. PI SZ individuals are technically eligible for augmentation therapy if their serum levels are below 11  $\mu\text{M}$ . However, it is unclear if PI SZ individuals with one or more measured serum values below 11  $\mu\text{M}$  have a different risk of COPD than PI SZ subjects with serum values above 11  $\mu\text{M}$ ; as noted above, the primary genetic determinant of AAT level is the PI type, and the significance of variation in serum level within a PI type has not been determined. AAT augmentation therapy is not indicated in PI MZ individuals.

At this time, AAT augmentation therapy is not recommended for severely deficient subjects with normal pulmonary function and without emphysema for the following reasons: (1) there is no compelling evidence that AAT augmentation therapy prevents the development of emphysema; (2) augmentation therapy is a very expensive treatment that requires weekly (or at least monthly) intravenous infusions; and (3) the subset of PI Z subjects

with preserved pulmonary function who will eventually develop COPD cannot be identified with certainty. PI Z subjects with normal pulmonary function but radiological evidence of emphysema represent a problematic group, in which the decision regarding augmentation therapy is controversial.

A variety of additional specific treatments have been considered for severe AAT deficiency. Recombinant AAT avoids the potential risks associated with a blood product, but the half-life of intravenous recombinant AAT, which lacks carbohydrate side chains, is considerably shorter than AAT prepared from plasma. To address this problem and to provide a more convenient mode of administration, aerosolized recombinant AAT was developed and shown to increase the antielastase capacity of the lung (141). Aerosolized treatment with Prolastin-C has also been shown to have biochemical efficacy (142); in a study of 30 normal volunteers who received 200 mg of aerosolized Prolastin-C, the medication was tolerated well and provided an increase in the antielastase activity of bronchoalveolar lavage fluid for at least 36 h after the dose was given (143). However, inhaled AAT has not been approved by the FDA.

Synthetic leukocyte elastase inhibitors have also been developed, but they have not yet been released for treatment purposes. Surgical treatments for COPD, which are not specific for AAT deficiency, such as lung volume reduction surgery and lung transplantation, have also been used in AAT-deficient patients with severe COPD.

### 60.5.8 Who should Be Tested for AAT Deficiency?

Selection of individuals for AAT deficiency testing involves a variety of complex issues. Severe AAT deficiency is associated with increased risks of COPD and liver cirrhosis, but the magnitude of these risks is uncertain. Specific treatment for AAT-related lung disease is available in the form of augmentation therapy but it is expensive and of uncertain therapeutic efficacy. Smoking cessation is beneficial for AAT-deficient subjects, but it is unknown if revealing the diagnosis of AAT deficiency will result in significantly increased rates of smoking cessation.

One study that suggested a beneficial effect of AAT screening for smoking avoidance in PI Z subjects resulted from the large newborn screening effort in Sweden (144). Follow-up of 50 PI Z children, who were diagnosed with AAT deficiency at birth, when they were 18–20 years old, found self-reported current smoking in 6% and exsmoking in 6% of these PI Z young adults. Among 48 matched control subjects, 17% were current smokers and 19% were exsmokers; these smoking rates were significantly higher than the rates for the PI Z subjects. Although smoking rates in PI Z individuals identified at birth appear to have been positively affected by

diagnosing AAT deficiency, there were concerns about the psychological impact on families of learning that their newborn had AAT deficiency (145). In light of these issues, general population screening for AAT deficiency has not yet been widely accepted.

In the American Thoracic Society's "Standards for the diagnosis and care of patients with chronic obstructive pulmonary disease," a relatively restrictive set of indications for AAT testing was presented (146). AAT testing was recommended for individuals in each of the following categories: (1) nonsmokers with chronic bronchitis and airflow obstruction; (2) bronchiectasis; (3) moderate or severe COPD by age 50; (4) basilar predominance of emphysema; (5) unremitting asthma, especially if under age 50; (6) family history of AAT deficiency or early-onset COPD; and (7) cirrhosis without apparent risk factors.

More recently, a Task Force of the American Thoracic Society and European Respiratory Society prepared a new set of standards for the diagnosis and management of AAT deficiency (69). In recognition of the marked underdetection of AAT deficiency and the fact that there are no studies of the efficacy of genetic testing programs in AAT-deficient subjects, they weighed the available evidence and provided recommendations. One of the most interesting and potentially controversial recommendations is for AAT testing of all symptomatic adults with COPD, emphysema, and/or asthma with irreversible airflow obstruction. This recommendation for widespread targeted detection efforts among individuals with chronic airflow obstruction represents a substantial change in clinical practice. Additional strong recommendations for AAT testing were provided for individuals with unexplained liver disease, individuals with necrotizing panniculitis (a rare manifestation of severe AAT deficiency), and siblings of PI Z subjects, who typically have a 25% risk of also having the PI Z type.

Currently, in the United States, only a minority of COPD patients who are diagnosed at later ages are tested for AAT deficiency. Testing additional people with COPD does raise significant economic and social issues; however, acceptance of a more uniform approach to screening for AAT deficiency would certainly be desirable.

### 60.5.9 Lessons from Severe AAT Deficiency

Although most subjects with COPD are not AAT deficient, AAT deficiency serves as an example of the manner in which genetic factors can predispose to COPD and a model of how genetic and environmental factors can interact. The identification of genetic factors predisposing to a disease can provide important insights into disease pathophysiology. The recognition of an association between heritable AAT deficiency and pulmonary emphysema was a central event in the development of the protease–antiprotease hypothesis for the pathogenesis

of emphysema (105). In addition to contributing to the development of this pathogenetic model of emphysema, AAT deficiency is an important risk factor for the development of COPD in a small minority of COPD patients. Searching for additional genetic factors influencing COPD may provide novel insights into the pathogenesis of COPD and other obstructive airways diseases, which potentially could lead to important therapeutic or preventative strategies.

## 60.6 RISK OF COPD IN Z ALLELE HETEROZYGOTES

### 60.6.1 PI MZ

The risk of lung disease in heterozygous PI MZ individuals has been a subject of considerable controversy for many years. PI MZ individuals do have reduced serum AAT concentrations (approximately 60% of PI M levels). However, random population surveys (including a study by Bruce et al. that matched subjects for age, race, sex, and smoking history), have typically found no differences in pulmonary function between PI MZ and PI M individuals (147,148). A study by Larsson et al. showed that PI MZ individuals who smoke cigarettes show some deficits in sensitive pulmonary function tests compared to smoking PI M subjects, but there was no evidence for increased airflow obstruction in smoking PI MZ subjects (assessed by the ratio of FEV<sub>1</sub> to vital capacity) (149). Larsson et al. did not find any significant differences in pulmonary function between nonsmoking PI M and PI MZ individuals. On the other hand, case–control studies comparing the prevalence of the PI MZ type in patients with COPD and control subjects have usually discovered an excess of PI MZ individuals among COPD patients (62,150,151).

Many of the previous studies that have attempted to assess the potential risk to PI MZ subjects have been limited by small sample size. Seersholm et al. matched 1551 PI MZ subjects from the Danish Alpha 1-antitrypsin Deficiency Registry with control subjects from the Danish general population (with 10 controls for each PI MZ subject). Using the Danish Hospital Discharge Registry, they compared the rates of hospitalization for obstructive lung diseases among the PI MZ and control subjects (152). The PI MZ subjects were significantly more likely to be hospitalized for asthma, emphysema, and chronic bronchitis than the control subjects; however, this increased risk for hospitalization was limited to the 565 subjects who were first-degree relatives of PI Z subjects with severe COPD. This study is limited by the lack of data related to smoking history on the PI MZ and control subjects, but the results suggest that the subset of PI MZ subjects who are first-degree relatives of PI Z subjects with COPD may be at increased risk for obstructive lung disease. The relative importance of PI MZ versus other

familial factors in determining the risk for COPD in the study by Seersholm et al. is uncertain.

In a study of 9187 adults in the Copenhagen City Heart Study, Dahl et al. found a slightly faster rate of FEV<sub>1</sub> decline among PI MZ subjects (25 mL/year) than among PI M subjects (21 mL/year) ( $P=0.048$ ) (153). However, in a general population sample of 2016 adults in Arizona, Silva et al. found no evidence for accelerated decline in FEV<sub>1</sub> among PI MZ compared to PI M subjects (154).

In an effort to synthesize the results from many studies that have examined PI MZ risk for COPD, Hersh et al. recently performed a meta-analysis (155). Among case-control and cross-sectional studies that compared the presence or absence of COPD among PI MZ and PI M subjects, a significantly increased risk of COPD among PI MZ subjects was found (odds ratio, 2.3; 95% CI, 1.6–3.4). However, among population-based studies that compared FEV<sub>1</sub> values between PI MZ and PI M subjects, no differences in average FEV<sub>1</sub> were found. Since COPD is defined by reductions in FEV<sub>1</sub>, the discordance between the results for COPD and FEV<sub>1</sub> was surprising. It is possible that all PI MZ subjects have a slightly increased risk for COPD, or that there is a significant risk for a subset of PI MZ subjects because of gene–gene or gene–environment interactions. Sørheim et al. examined the associations between PI MZ heterozygosity and COPD-related phenotypes in two large populations: a case-control study from Norway and a multicenter family study from Europe and North America (156). In this study, they demonstrated that PI MZ heterozygotes had lower FEV<sub>1</sub>/FVC ratio than PI MM individuals, suggesting that PI MZ individuals may be slightly more susceptible to the development of airflow obstruction than PI MM individuals.

### 60.6.2 PI SZ

The risk of COPD associated with the PI SZ type is also uncertain. PI SZ subjects have serum AAT levels that are approximately 35% of PI MM levels (157). Turino et al. evaluated 50 PI SZ individuals from the NHLBI Alpha 1-antitrypsin Deficiency Registry who provided spirometric data (158). PI SZ subjects who were lifelong nonsmokers had airflow obstruction less frequently than lifelong nonsmoking PI Z subjects. Among smokers, PI SZ and PI Z subjects had similar levels of pulmonary function impairment. However, 50% of these PI SZ subjects were identified because they had lung disease. More recently, Holme et al. demonstrated that subjects with PiSZ showed less emphysema on CT scans and less abnormal respiratory physiology test results (159). However, both the PiSZ and the PiZZ groups had similar health status impairment. The reasons for this finding remain unclear.

Seersholm and Kok-Jensen assessed 94 PI SZ subjects ascertained from the Danish Alpha 1-antitrypsin

Deficiency Register (160); they included 28 index cases who were identified because they had respiratory problems and 66 nonindex cases who were identified through family studies. Nonindex PI SZ subjects had no increased mortality compared to population norms, and the mean FEV<sub>1</sub> of this group was 94.7% predicted. In a series of 25 PI SZ subjects, Hutchison et al. found FEV<sub>1</sub> below 80% predicted in 11 of 14 index PI SZ subjects who were identified through a chest clinic, but only in 1 of 11 non-index PI SZ subjects who were identified through family studies (157). In summary, PI SZ subjects ascertained with lung disease, not surprisingly, have reduced pulmonary function; PI SZ subjects who are not ascertained because of pulmonary problems often have preserved pulmonary function. Whether PI SZ subjects are at significantly increased risk for COPD, even if they smoke, has not been definitively established.

## 60.7 COPD AND COPD-RELATED PHENOTYPES IN OTHER GENETIC SYNDROMES

Several rare genetic syndromes are associated with COPD or have COPD-like features. Cutis laxa is a rare syndrome associated with loose, redundant, and inelastic skin. Several modes of inheritance of cutis laxa have been described. Autosomal-recessive cutis laxa is often associated with emphysema, even in childhood. At least some cases of autosomal-recessive cutis laxa are caused by mutations in the fibulin-5 (*FBLN5*) gene (161). Fibulin-5 is critical for normal elastic fiber development, and fibulin-5 knockout mice develop severe emphysema (162,163).

Autosomal-dominant cutis laxa can be caused by frameshift mutations in the distal part of the elastin (*ELN*) gene; although emphysema has been less consistently reported in autosomal-dominant than autosomal-recessive cutis laxa, several individuals with autosomal-dominant cutis laxa and emphysema have been reported (164,165). A novel mutation in the fibulin-4 gene (*FBLN4*; 11q13) was recently identified in autosomal-recessive cutis laxa with developmental emphysema (166). The mutation caused an amino acid substitution in an epidermal-growth-factor-like domain of fibulin-4, leading to very low levels of extracellular protein.

Another rare genetic syndrome potentially related to the development of emphysema is familial spontaneous pneumothorax, which has been described in multiple families. Recently, an extended pedigree from Finland was included in a genome-wide linkage study; suggestive linkage of familial spontaneous pneumothorax to chromosome 17p was found (167). The linkage peak was located near the folliculin gene (*FLCN*); mutations in the *FLCN* gene can lead to Birt–Hogg–Dube Syndrome—a rare syndrome associated with cystic lung changes. In the Finnish pedigree with familial spontaneous

pneumothorax, a 4-bp deletion in the *FLCN* gene was found to correlate perfectly with emphysema-like cystic lung changes on chest CT scan. The relationship of these cystic lung changes to airflow obstruction was not discussed.

Menkes disease is a condition characterized by abnormal hair and dysmorphic features and caused by mutations in an intracellular copper transporter (*ATP7A*; Xq13.3). The clinical features are due to defective connective tissue synthesis probably because of the result of dysfunction of lysyl oxidase. This copper-dependent enzyme is required for proper cross-linking of both collagen and elastin fibers. A recent case report described a child with Menkes disease and severe bilateral pan-lobular emphysema who died at the age of only 14 months (168). Gene sequencing revealed a splice-site mutation in *ATP7A*, suggesting that proper ECM cross-linking is vital for stability of the lung parenchyma.

Although rare genetic syndromes such as cutis laxa, familial spontaneous pneumothorax, and Menkes disease account for a tiny fraction of COPD cases, they may point to pathways relevant for the development of COPD in the general population.

## 60.8 RISK TO RELATIVES FOR NON-AAT COPD

### 60.8.1 Familial Aggregation of Spirometry and COPD

Several types of studies have suggested that genetic factors other than AAT type may be involved in the susceptibility to develop COPD. We review the evidence from general population studies and from COPD families; subsequently, we consider severe, early-onset COPD.

A variety of studies of pulmonary function measurements performed in the general population and in twins have suggested that genetic factors influence variation in pulmonary function. Redline et al. assessed spirometry in 256 monozygotic and 158 dizygotic twins who were not selected for respiratory problems (169). For FEV<sub>1</sub>, higher correlation in monozygotic twins (0.72) than dizygotic twins (0.27) suggested that genetic factors influence variation in pulmonary function. However, such general population studies do not address whether genetic factors influence the development of significant airflow obstruction.

Studies in relatives of COPD patients also have supported a role for genetic factors. Several studies in the 1970s reported higher rates of airflow obstruction in first-degree relatives of COPD patients than in control subjects. For example, Larson et al. compared spirometry in 156 first-degree relatives of COPD patients to 86 spouse controls with similar pack-year history of smoking (170). Airflow obstruction was found in 23% of first-degree relatives, but only 9% of control subjects.

Although this study did show familial aggregation for airflow obstruction, it had several weaknesses. AAT deficiency was not rigorously excluded as a potential contributor to airflow obstruction. In addition, a higher percentage of the first-degree relatives than controls were smokers, so at least some of the observed differences may relate to differences in smoking behavior. Nonetheless, genetic predisposition to COPD was suggested by this study.

Kueppers et al. studied 114 subjects with COPD and control subjects matched based on age, gender, occupation, and smoking history (171). Siblings of COPD and control subjects also were included; the mean FEV<sub>1</sub> among siblings of COPD subjects (90% of predicted) was significantly lower than the siblings of control subjects (103% of predicted). This difference in pulmonary function between siblings of COPD and control subjects remained significant after adjustment for smoking history.

A large study of COPD in families was performed at Johns Hopkins (172,173). Familial aggregation for airflow obstruction was demonstrated; after adjusting for age, sex, race, and smoking history, reduced FEV<sub>1</sub>/FVC was found in 28% of first-degree relatives of COPD probands compared with 19% of relatives of nonpulmonary patients (173). The high rate of airflow obstruction in the relatives of nonpulmonary patients is unexplained. Variance component analysis of their data suggested a significant genetic contribution to FEV<sub>1</sub> and the ratio of FEV<sub>1</sub>/FVC (174).

More recently, McCloskey et al. assessed familial aggregation of airflow obstruction in 173 siblings of probands with severe COPD compared to a population-based control cohort in the United Kingdom (175). None of the nonsmoking siblings had evidence for airflow obstruction on spirometry. However, smoking siblings of COPD probands had a significantly increased risk of airflow obstruction compared to matched population-based control subjects, with an odds ratio of 4.7 ( $P < 0.0001$ ).

Additional studies have demonstrated familial aggregation of chronic bronchitis. In a survey of 9226 residents of Tecumseh, Higgins and Keller found approximately threefold higher rates of chronic bronchitis in offspring when at least one parent had chronic bronchitis than if neither parent had chronic bronchitis; this analysis did not include adjustment for cigarette smoking (176). Speizer et al. analyzed National Health Interview Survey data from 1970 for chronic respiratory conditions and found higher rates of bronchitis or emphysema among offspring when at least one parent had bronchitis or emphysema; this effect appeared to be independent of cigarette smoking (177). Finally, in a study in East Boston, Tager et al. found approximately twofold higher rates of chronic bronchitis or airflow obstruction in first-degree relatives of probands with chronic bronchitis or airflow obstruction than in first-degree relatives of

control probands; this familial aggregation also appeared to be independent of cigarette smoking (178).

### 60.8.2 Familial Aggregation of Severe, Early-Onset COPD

In an effort to identify novel genetic risk factors for COPD, Silverman et al. have focused on subjects with severe, early-onset COPD unrelated to severe AAT deficiency (179). In multiple previous successful studies of complex trait genetics, focusing on early-onset cases led to the identification of susceptibility genes for breast cancer, Alzheimer's disease, glaucoma, and diabetes mellitus (maturity-onset diabetes of the young) (180–184). By studying severe, early-onset COPD probands and their relatives, the study population may be enriched for genetic influences.

Probands in the Boston early-onset COPD study had FEV<sub>1</sub> <40% predicted at age younger than 53 years, without severe AAT deficiency (179). All available first-degree relatives, spouses, and older second-degree relatives (aunts, uncles, and grandparents) were included. The initial phase of the Boston early-onset COPD study included 44 early-onset COPD probands, with 204 first-degree relatives, 54 second-degree relatives, and 20 spouses. Spirometric and demographic data for the first-degree relatives of early-onset COPD probands, stratified by smoking status, are shown in Table 60-2. Highly significant differences in FEV<sub>1</sub> and FEV<sub>1</sub>/FVC were found when current or exsmoking first-degree relatives of early-onset COPD probands were compared to control subjects. No significant differences in age or pack-years of smoking were noted.

No significant differences in FEV<sub>1</sub> or FEV<sub>1</sub>/FVC were found when lifelong nonsmoking first-degree relatives of early-onset COPD probands were compared to lifelong nonsmoking control subjects. In fact, the mean FEV<sub>1</sub> values were 93.4% of predicted in both groups of nonsmokers. This pattern would be consistent with genetic risk factors that interact with smoking to result in COPD. A similar pattern of smoking-related susceptibility was also seen for chronic bronchitis (179). To account for potential familial correlations and for the effects of age and pack-years of smoking, generalized estimating

equations were used to calculate odds ratios of developing chronic bronchitis and various levels of reduction in FEV<sub>1</sub>. When all first-degree relatives of early-onset COPD probands were compared to all controls, an increased risk of FEV<sub>1</sub> <80% was seen. However, stratification by smoking status revealed that this risk was exclusively found in smoking first-degree relatives; with significant odds ratios of 4.5 for FEV<sub>1</sub> <80% predicted and 3.6 for chronic bronchitis, and a nearly significant odds ratio of 3.5 for FEV<sub>1</sub> <60% predicted. Lifelong nonsmokers had no increased risk for reduced FEV<sub>1</sub> or chronic bronchitis. Smoking-related increased spirometric bronchodilator responses were also observed in smoking first-degree relatives of severe, early-onset COPD probands compared to smoking control subjects (185). Subsequent analyses of an increased number of first-degree relatives in the Boston early-onset COPD study have shown that nonsmoking first-degree relatives of severe, early-onset COPD probands do have significantly lower values of some more sensitive spirometric measures (e.g. FEF<sub>25–75</sub>) compared to nonsmoking control subjects, suggesting that even nonsmoking first-degree relatives of severe, early-onset COPD probands may have mild airflow abnormalities (186).

A remarkably high percentage of females (>70%) was noted among the early-onset COPD probands (187). This female predominance differed from previous studies of severe COPD, which had found a male predominance (188–191). The explanation for the female predominance found by Silverman et al. is uncertain but this study included a group of probands who were younger, more severely affected, and more recently collected than earlier series of severe COPD subjects. In a follow-up study of these severe, early-onset COPD probands, reduced survival of male subjects with severe COPD did not appear to account for the observed female predominance (192); thus, it is certainly possible that there is a biological basis for the increased female susceptibility, due to hormonal or other factors, that could mediate a genotype-by-gender interaction in early-onset COPD pedigrees.

In summary, the Boston early-onset COPD study has led to the identification of a variety of phenotypes that demonstrate smoking-related susceptibility in first-degree

**TABLE 60-2 Age, Smoking History and Spirometry in First-Degree Relatives of Boston Early-Onset COPD Study Probands Compared to Control Subjects<sup>a</sup>**

Group	n	FEV <sub>1</sub> /FVC (% Pred)	FEV <sub>1</sub> (% Pred)	Age	Pack-Years

relatives of early COPD probands including FEV<sub>1</sub>, FEV<sub>1</sub>/FVC, chronic bronchitis, FEF<sub>25–75</sub>, and bronchodilator responsiveness. These phenotypes will probably be useful in further genetic studies of COPD.

## 60.9 SEGREGATION ANALYSIS

Segregation analysis is a statistical technique that attempts to determine if the pattern of phenotypes within families is consistent with the transmission of a major gene for that phenotype. Segregation analysis has been performed with spirometric phenotypes in several general population studies. Chen et al. performed segregation analysis with class D regressive models in a general population sample of 799 individuals from 214 nuclear families in Saskatchewan (193). They found no evidence for a major gene effect for FEV<sub>1</sub> or FEF<sub>25–75</sub>. Givelber et al. performed segregation analysis of FEV<sub>1</sub> with class D regressive models in 5003 individuals from 1408 pedigrees in the Framingham Study (194). They took advantage of the longitudinal follow-up of Framingham families by selecting spirometric values from parents in the 1960s and offspring in the 1990s; thus, spirometric values from parental and offspring generations were compared at similar ages. Although they found evidence for significant familial correlations for FEV<sub>1</sub>, they did not demonstrate evidence for a major gene influencing FEV<sub>1</sub>. Wilk et al. also used class D regressive models to perform segregation analysis in 1964 Caucasian individuals in 455 families (195). They found evidence for a dominant major gene influencing FEV<sub>1</sub>. In summary, segregation analysis of pulmonary function measurements in the general population has supported genetic influences, but they have provided inconsistent evidence for major gene effects.

In COPD families, the Johns Hopkins COPD study included segregation analysis of spirometric phenotypes. The investigators found support for the existence of a major gene influencing FEV<sub>1</sub> in families with COPD (196). However, they performed segregation analysis with class A regressive models, which subsequently have been shown to be susceptible to false-positive assignments of major genes when they are applied to quantitative traits such as FEV<sub>1</sub> (197).

Segregation analysis has also been performed in AAT-deficient families to determine if there is evidence for an additional major gene influencing pulmonary function in those families (198). To determine if the variability in pulmonary function among AAT-deficient families was determined by environmental factors or genetic factors other than PI type, segregation analysis was performed after adjustment for the effects of PI type on the mean and variance of spirometric measures. Segregation analysis, performed with the mixed model incorporated in the POINTER computer program, provided preliminary evidence for an additional major gene influencing FEV<sub>1</sub>. However, significant evidence for an

additional major gene could not be demonstrated after the effects of cigarette smoking and the interaction of cigarette smoking with PI type were included. Although the failure to demonstrate evidence for a major gene after adjustment for cigarette smoking may indicate that the effect of smoking provided false evidence for a major gene initially, these results could indicate the existence of a major gene that enhances susceptibility to the effects of cigarette smoking. Thus, the presence of additional genetic factors influencing the development of COPD in PI Z individuals, potentially mediated by variable susceptibility to smoking, remains intriguing but speculative.

## 60.10 LINKAGE ANALYSIS

### 60.10.1 Linkage Analysis in COPD Families

In the Boston early-onset COPD study, 585 members of 72 early-onset COPD pedigrees were included in genome-wide linkage analysis. Initially, qualitative COPD-related phenotypes of airflow obstruction and chronic bronchitis were analyzed with multipoint non-parametric linkage analysis (199). In the initial qualitative phenotype genome scan, no genomic regions met criteria for suggestive linkage to airflow obstruction or chronic bronchitis (200). However, limiting analysis to cigarette smokers substantially increased the evidence for linkage of chronic bronchitis to chromosome 22 (LOD = 2.08 at 36 cM).

Genome-wide linkage analysis of quantitative spirometric phenotypes provided more compelling evidence for linkage, especially using postbronchodilator spirometric values (201,202). Postbronchodilator FEV<sub>1</sub> showed at least suggestive evidence for linkage to chromosome 8p (LOD = 3.30 at 2 cM) and 1p (LOD = 2.24 at 136 cM). Postbronchodilator FEV<sub>1</sub>/FVC was also linked to multiple regions, most significantly to markers on chromosome 2q (LOD = 4.42 at 222 cM) and 1p (LOD = 2.52 at 118 cM).

Genotyping additional short tandem repeat (STR) markers to increase the genotypic information for linkage analysis provided stable to increased evidence for linkage of quantitative spirometric phenotypes on chromosomes 2q, 12p, and 19q (203,204). Stratified linkage analysis of smokers only also provided stable to increased evidence for linkage to these genomic regions, potentially related to genotype-by-smoking interactions.

### 60.10.2 Linkage Analysis of Pulmonary Function in the General Population

Genome-wide linkage studies of spirometric measures have also been performed in families from the general population (summarized in Table 60-3). In the Framingham Study, Joost et al. analyzed quantitative prebronchodilator spirometric measurements in 1578

**TABLE 60-3 Linkage Analysis of Quantitative Spirometric Phenotypes in the General Population<sup>a</sup>**

Author (Date)	Population (n)	FEV <sub>1</sub>		FEV <sub>1</sub> /FVC	
		Region	Maximum LOD	Region	Maximum LOD
Joost (2002) (205)	Framingham study (n = 1578)	4p	1.6	—	—
		6q	2.4	—	—

				4p	2.6 <sup>b</sup>
				8p	1.6 <sup>b</sup>
				11q	1.9 <sup>b</sup>
				15q	1.6 <sup>b</sup>
Malhotra (2003) (207)	CEPH Pedigrees (n = 264)			2q	2.0
				5q	2.2 <sup>c</sup>

<sup>a</sup>LOD scores above 1.5 are presented.<sup>b</sup>On the basis of normalized phenotypic values for FEV<sub>1</sub>/FVC.<sup>c</sup>Corresponds to parametric heterogeneity LOD score.

individuals from 330 pedigrees using variance component linkage analysis (205). They found suggestive linkage of FEV<sub>1</sub> to chromosome 6q (LOD = 2.4). After genotyping additional STR markers in a subset of their study population, increased evidence for linkage to FEV<sub>1</sub> to 6q was found (LOD = 5.0) (206).

With 2178 participants in the Family Heart Study, Wilk et al. performed genome-wide linkage analysis with prebronchodilator spirometric phenotypes including FEV<sub>1</sub> and FEV<sub>1</sub>/FVC (195). They found suggestive evidence for linkage of FEV<sub>1</sub> to chromosome 3q and FEV<sub>1</sub>/FVC to chromosome 4p. Of interest, they also demonstrated some evidence for linkage of FEV<sub>1</sub>/FVC to chromosome 1p (LOD = 1.8) near the region of linkage to FEV<sub>1</sub>/FVC in the Boston early-onset COPD study.

Using 26 extended Centre d'Etude du Polymorphisme Humain (CEPH) pedigrees, Malhotra et al. also performed genome-wide linkage analysis of prebronchodilator spirometric measurements (207). They found suggestive evidence for linkage of FEV<sub>1</sub>/FVC to chromosome 2q in a similar region to the significant FEV<sub>1</sub>/FVC linkage reported in the Boston early-onset COPD study, as well as suggestive linkage of FEV<sub>1</sub>/FVC to chromosome 5q.

The linkage results of spirometric measurements in the Boston early-onset COPD study pedigrees and general population pedigrees have been somewhat inconsistent, except for the FEV<sub>1</sub>/FVC linkage to chromosome 2q in the CEPH pedigrees and the FEV<sub>1</sub>/FVC linkage to 1p in the Family Heart Study. Inconsistent linkage results between COPD families and general population pedigrees could relate to different genetic determinants influencing normal variation in spirometry and COPD, false-positive evidence for linkage in some regions, and/or inadequate power to replicate all linkage signals in the different studies.

Silverman's group reported a genome-wide linkage analysis in the Boston early-onset COPD study, which found significant linkage to a region on chromosome 2q for COPD-related traits (201,203). DeMeo et al. identified *SERPINE2* as a COPD-susceptibility gene

on chromosome 2q (208). Single nucleotide polymorphisms (SNPs) in *SERPINE2* were demonstrated to explain some of the chromosome 2q linkage signal. In addition, the presumed functional variant(s) in *SERPINE2* have yet to be identified. Furthermore, chromosome 2q was also linked to lung function traits in a general population sample of 264 individuals in 26 families from Utah (207) and in a Dutch study of 1183 individuals in 200 families ascertained through a proband with asthma (209). This suggests that additional COPD-susceptibility genes are located on chromosome 2q and that these genes can be identified by merging SNP-based fine mapping data from multiple COPD study populations. Hersh et al. identified *XRCC5*, an ATP-dependent DNA helicase, as a potential COPD-susceptibility gene by genotyping SNPs in the chromosome 2q region in four study samples—two case-control and two family-based—and tested for association with COPD and related traits (210).

## 60.11 GENETIC ASSOCIATION STUDIES

A large number of association studies have compared the distribution of variants in candidate genes hypothesized to be involved in the development of COPD in COPD patients and control subjects. For example, Smith and Harrison demonstrated associations between two polymorphisms in the microsomal epoxide hydrolase gene (*EPHX1*) with COPD by comparing two groups of COPD patients to 203 blood donors in Scotland (211). They included 94 patients with pathologically demonstrated emphysema from lung tissue surgically resected during lung cancer surgery; they also included a group of 68 patients with COPD from a respiratory clinic. Previously, a variant in exon 3 had been associated with reduced *EPHX1* activity compared to wild-type, while a variant in exon 4 had been associated with increased *EPHX1* activity compared to wild-type. Because *EPHX1* is involved in the metabolism of reactive epoxide intermediates, which can be produced by cigarette smoke

exposure, these functional variants were hypothesized to be involved in the variable development of COPD. In comparisons across genotypes, the 68 COPD patients and the 94 pathologically proven emphysema patients were each more likely to include homozygotes for the slow allele in exon 3. However, these authors also found an association of the variant allele in exon 4, conferring fast enzyme activity, with COPD in the respiratory clinic patients. Thus, the functional significance of reduced *EPHX1* activity is unclear.

A variety of candidate genetic loci have been studied with the case-control association analysis approach. A nonexhaustive list of loci that have been associated with COPD is presented in Table 60-4. A representative study supporting the association is shown for polymorphic variants located beyond the 3' end of the AAT gene, the vitamin D-binding protein, the cystic fibrosis transmembrane regulator gene, ABO blood group, alpha 1-antichymotrypsin, and ABH secretor status (172,212–215). In some cases, more than one study exists to support an association. However, in each case, at least one study refutes the association (216–219).

Several factors could contribute to the inconsistent results of case-control genetic association studies in COPD. Genetic heterogeneity in different populations could contribute to difficulty in replicating associations between studies. In addition, false-positive or false-negative results could contribute to inconsistent replication. A potentially important factor is that case-control association studies are susceptible to supporting associations based purely on population stratification (220). Population stratification can result from incomplete matching between cases and controls, including differences in ethnicity and geographic origin. In addition, most published COPD genetic association studies have not focused on genomic regions linked to COPD-related phenotypes—regions in which association studies may be more fruitful.

Only one family-based genetic association study has been reported in COPD (204), a study design that is typically immune to population stratification effects. This study focused on genetic variants in *TGFB1*, a gene that is located within the region of linkage to FEV<sub>1</sub> on chromosome 19q in the Boston early-onset COPD study and that was associated with COPD in one previously

reported case-control genetic association study (221). Five *TGFB1* SNPs were genotyped in Boston early-onset COPD study families; using family-based association analysis, one SNP in the promoter region of *TGFB1* (rs2241712) and two SNPs in the 3' untranslated region of *TGFB1* (rs2241718 and rs6957) were significantly associated with FEV<sub>1</sub> ( $P < 0.05$ ). Among 304 severe COPD cases from the National Emphysema Treatment Trial (NETT) and 441 smoking control subjects from the Normative Aging Study (NAS), two SNPs in the promoter region of *TGFB1* (rs2241712 and rs1800469) and one SNP in exon 1 of *TGFB1* (rs1982073) were significantly associated with COPD ( $P \leq 0.02$ ) (204). Additional research to replicate the genetic associations in *TGFB1* and to identify the functional variants in or near *TGFB1* will be required. Genetic variation in *TGFB1* is also a modifier of the lung involvement in classic cystic fibrosis.

The Framingham Heart Study has collected spirometry and smoking history data on three generations of adults, and these research participants provided DNA samples that have recently been genotyped for 550,000 SNPs using microarray technology. These genotype and phenotype data, which have been made publicly available through the NHLBI's SNP Health Association Resource (SHARe) initiative, provide a powerful resource to conduct genome-wide association studies to identify novel genetic risk factors for airflow obstruction. Wilk et al. performed a genome-wide association study in 7691 Framingham Heart Study participants to identify SNPs associated with the FEV<sub>1</sub>/FVC ratio, analyzed as a percentage of the predicted value (222). Four SNPs in tight linkage disequilibrium on chromosome 4q31 were associated with the percentage predicted FEV<sub>1</sub>/FVC ratio with  $P$  values of genome-wide significance in the Framingham sample (best  $P$  value =  $3.6 \times 10^{-9}$ ). Quantitative spirometry traits were examined in a previous genome-wide association study using 70,987 SNPs in about 1220 related individuals in the Framingham Heart Study (223). Although no results met the strict criteria for genome-wide significance, *GSTO2* emerged as a candidate gene that warranted replication studies.

Matrix metalloproteinase (MMP)-12-mediated pathologic degradation of the extracellular matrix and the subsequent repair cycles influence the airway changes in

patients with COPD and asthma. Haplotypes containing the MMP12 Asn357Ser (rs652438) allele are associated with lung function decrease in smokers with COPD (224). Recently, Mukhopadhyay et al. demonstrated that the common serine variant at codon 357 of the MMP12 gene (rs652438) is associated with increased severity of in patients with COPD (225).

Thus far, a variety of candidate genes have been examined in COPD with genetic association studies, but no genetic loci other than SERPINA1 (AAT) have been definitively proven as significant risk factors for COPD.

## 60.12 ANIMAL MODELS OF COPD

Animal models have played an important role in the elucidation of emphysema pathophysiology. In 1964, Gross et al. were assessing the effects of intratracheal injection of a variety of substances, including papain, human serum, and tap water, on the development of silicosis in a rat model (226). Surprisingly, the animals treated with papain developed severe emphysema, which was not detected in the other experimental groups. The development of emphysema was related to the proteolytic activity of papain; subsequently, a variety of other proteolytic enzymes, including leukocyte elastase and proteinase 3, have been shown to cause experimental emphysema in rodents following intratracheal instillation (227). The proteolytic cleavage of elastin appears to be critical for the development of protease-induced experimental emphysema. This work has provided critical evidence for the protease–antiprotease hypothesis for the development of emphysema—particularly regarding the importance of elastase and antielastase activities to this hypothesis.

Advances in molecular biological techniques have led to a variety of creative applications of animal models in COPD research. Transgenic mice that overexpress interstitial collagenase (MMP1) develop histologic changes of emphysema (228). These interstitial collagenase transgenic mice do not have associated inflammation or a decrease in elastin fibers. Therefore, it is unclear if the MMP1 transgenic model represents a failure of alveolar septation in development or if it corresponds to adult-onset emphysema. However, transgenic mice that inducibly overexpress interleukin-13 develop emphysema and inflammation, with characteristics more similar to

human COPD (229). Transgenic mice that inducibly overexpress interferon gamma in the adult lung also develop emphysema and inflammation (230). Both the interleukin-13 and interferon gamma transgenic mouse models demonstrate increased activity of a variety of cathepsins and MMPs.

“Knockout” mouse models have also provided useful insights into COPD pathophysiology. Macrophages from a macrophage elastase knockout mouse had impaired ability to invade extracellular matrix and degrade elastin (231). Subsequently, Hautamaki et al. compared the effects of cigarette smoke exposure on these macrophage elastase knockout mice with their wild-type litter mates (232). In wild-type animals, macrophage elastase was only expressed in mice that had been exposed to cigarette smoke; these smoke-exposed wild-type mice developed emphysema after 6 months of cigarette smoke exposure. However, macrophage elastase knockout mice did not develop emphysema after 6 months of cigarette smoke exposure. The changes in alveolar duct area and mean linear intercept in wild-type and macrophage elastase knockout mice are demonstrated in Table 60-5.

To demonstrate that the development of emphysema was not simply a reflection of the increased number of lung macrophages in smoke-exposed mice, Hautamaki et al. instilled monocyte chemoattractant protein-1 intratracheally into the macrophage elastase knockout mice. Although the number of pulmonary macrophages increased substantially in response to monocyte chemoattractant protein-1 instillation, the macrophage elastase knockout mice still did not develop emphysema with cigarette smoke exposure. The importance of macrophage elastase in human emphysema remains to be determined, but it is an attractive candidate proteinase in COPD pathophysiology.

Other knockout mice develop emphysema even without cigarette smoke exposure. Mice that underwent targeted disruption of the platelet-derived growth factor A chain developed lung hyperinflation and air-filled cavities; alveolar septation was absent (233). This developmental defect resulted from a failure of alveolar development with a lack of elastin fiber production, which was caused by an absence of alveolar myofibroblast cells. Knockout mice for the surfactant protein D (SFTPD), integrin  $\beta 6$  (ITGB6), and tissue inhibitor of metalloproteinase-3

(TIMP3) genes spontaneously develop progressive emphysema as they get older (234–236). Because these knockout animals develop inflammation with increased MMP activity, they may provide useful models to study COPD pathophysiology.

The klothe and fibroblast-growth-factor-23-deficient mice models both develop spontaneous emphysema as part of a “rapid aging” phenotype that is potentially related to perturbations of vitamin D metabolism (237,238). Tight-skin mice develop emphysema and features resembling Marfan syndrome due to a mutation in the fibrillin 1 gene (*FBN1*) (239).

While these monogenetic mouse models have provided insights into COPD pathogenesis, susceptibility for developing complex syndromes such as COPD are more likely to be the result of a combination of allelic variants that leave an individual more susceptible to the effects of cigarette smoke exposure. There have been several groups that have started to compare the degree of cigarette-smoke-induced lung damage among different strains of mice to understand the genetic factors that may underlie COPD susceptibility. The earliest approaches compared the effects of smoke exposure in a few mouse strains with differences in specific molecular phenotypic traits, i.e. different levels of AAT (240), different antioxidant responses (241), and different major histocompatibility complex haplotypes (242).

In addition to transgenic and knockout mouse models, several naturally occurring mouse models have emphysema-like features (243). One such spontaneously occurring mutation, the tight-skin mouse, was shown to result from a mutation in *FBN1* (244). This *FBN1* mutation interferes with elastic fiber assembly, resulting in enlarged airspaces; thus, it likely represents a developmental defect resulting in airspace enlargement rather than a destructive process of normally developed, mature lung tissue.

Although rodent models have provided important insights into potential biochemical mechanisms of COPD, identification of susceptibility loci using experimental crosses of relatively susceptible and relatively nonsusceptible strains with quantitative trait locus analysis has not yet been reported. Significant differences in susceptibility between murine strains to the development of smoking-induced COPD have been demonstrated (242). Utilization of these strain-specific differences in COPD susceptibility to perform quantitative trait locus mapping may provide unique opportunities to uncover genetic determinants of COPD (245).

### 60.13 CONCLUSIONS

Severe AAT deficiency is a proven genetic risk factor for COPD. Although considerable insight into the pathogenesis of COPD has been provided by studies of AAT deficiency, fundamental questions about the natural history of AAT deficiency remain unanswered.

Only a small percentage of COPD patients inherit severe AAT deficiency, and additional genetic factors likely influence the development of COPD. Further efforts in linkage analysis, association studies, and animal models may lead to the identification of such factors. To achieve a complete understanding of COPD pathophysiology, characterization of the interactions between genetic determinants and cigarette smoking (and potentially other environmental factors) will be required. Identification of genetic factors influencing the development of COPD unrelated to AAT deficiency could clarify the biochemical mechanisms causing COPD, allow identification of highly susceptible individuals, and lead to new therapeutic interventions for COPD.

## Biographies

**Dr Chad K Oh, MD** received his medical education at Kyung-Hee University School of Medicine in Seoul, Korea, and completed his pediatric residency training at the Rush University School of Medicine in Chicago, IL, and allergy immunology fellowship training at the National Institutes of Health in Bethesda, MD. He is certified by the American Board of Pediatrics and the American Board of Allergy and Immunology. He joined the faculty at UCLA in 1995 and was promoted through the assistant and associate Professor levels. He served as the Program Director of the Harbor-UCLA Conjoint Adult/Pediatric Clinical Immunology and Allergy Fellowship Training Program for six years. Dr Oh was the Chief of Allergy and Immunology Division at Harbor-UCLA Medical Center in Torrance, CA. He has authored more than 40 publications in prestigious journals, including *The Journal of Immunology*, *The Journal of Allergy and Clinical Immunology*, *Biochemical Journal*, and *Proceedings of the National Academy of Sciences USA*. He authored the book, “How to live with a nut allergy” by McGraw-Hill, as well as six other book chapters and 70 abstracts. Dr Oh has served as a member or chairman on numerous national committees and as an officer for professional organizations, including the Executive Committee of the American Academy of Allergy, Asthma and Immunology and the American College of Allergy, Asthma and Immunology, and as President of the Los Angeles Society of Allergy Asthma Immunology. He has served on the editorial board of *Experimental Medicine* and has been a reviewer for numerous journals, including *The Journal of Allergy and Clinical Immunology*, *The Journal of Immunology*, *Pediatrics*, and *Allergy & Asthma Proceedings*. Dr Oh has received several honors and awards, including young investigator awards from the National American Lung Association and an Innovative Research Award from the American Academy of Allergy, Asthma & Immunology. He joined MedImmune, LLC, in 2008 as a Medical Director to participate in the development of novel therapeutic targets in asthma and other lung diseases.

**Dr Néstor Molfino, MD, MSc, FCCP** joined MedImmune, LLC, in June 2007 as senior Director and was named Vice President, Clinical Development, and Clinical Therapeutic Area Head, Pulmonary Disease in July 2008. In this role, he is responsible for all phases of global clinical development for pulmonary conditions. Dr Molfino has 14 years of biopharmaceutical industry experience. Before joining MedImmune, Dr Molfino was senior Director, Clinical Development at Otsuka Maryland Research Institute for four years. He also served as Director, Medical Affairs at Baxter Bioscience and Vice President, Research and Development and Scientific Affairs at Theratechnologies, Inc, in Canada. For the past 14 years, Dr Molfino has also served as a pulmonary and allergy consultant to Fermin Salaberry, a nonprofit public community hospital in Argentina. Dr Molfino received a master's degree in molecular and cell biology from the University of Toronto. He holds a medical degree from Universidad Nacional de Rosario in Argentina, completing an internship and residency in internal medicine and respiratory medicine, after which he went to Toronto, Canada, for a postdoctoral fellowship at the University of Toronto, where he was appointed assistant professor in 2004. In 2006, he was also appointed adjunct professor at McGill University in Montreal, Canada.

## Interstitial and Restrictive Pulmonary Disorders

*William E Lawson and James E Loyd*

Division of Allergy, Pulmonary, and Critical Care Medicine, Vanderbilt University School of Medicine, Department of Veterans Affairs Medical Center, Nashville, TN, USA

This article is a revision of the previous edition article by Gunnar Gudmundsson and Gary W Hunninghake, volume 2, pp 1431–1444, © 2007, Elsevier Ltd.

### 61.1 INTRODUCTION

The interstitial lung diseases (ILDs) represent a heterogeneous group of lung disorders that are characterized by inflammation and/or fibrosis in the interstitial space between alveoli as well as adjacent perialveolar tissue and other contiguous supporting structures. In most instances, ILDs lead to restrictive physiology on pulmonary function testing (PFT) and many lead to hypoxemia and respiratory failure. Over 150 diseases have been associated with ILD, some with known causes that include environmental exposures such as asbestos, autoimmune and rheumatologic disease, and underlying genetic syndromes that include manifestations of ILD, several of which are covered in this chapter. However, a significant component of individuals with ILD actually fall into the idiopathic interstitial pneumonia (IIP) category, a group of ILDs in which the cause remains unknown. Over the past decade, evidence has emerged suggesting that at least a component of these IIPs may have a genetic basis, holding promise that one day the cause of these diseases will be known and targeted therapies developed. We have divided this chapter into three main categories: (1) the role of genetics in the IIPs, (2) common diseases that can include ILD as a manifestation and that likely have a genetic contribution to disease, and (3) defined genetic syndromes that include ILD as one manifestation.

### 61.2 IDIOPATHIC INTERSTITIAL PNEUMONIA AND FAMILIAL INTERSTITIAL PNEUMONIA

#### 61.2.1 Idiopathic Interstitial Pneumonia (IIP)

When a patient presents with a clinical presentation consistent with ILD, the physician must try to determine if an

underlying disease process explains the presence of ILD. However, in many instances, the cause of ILD remains unknown and the patient's diagnosis falls into a group of disorders known as the IIPs. By the latest American Thoracic Society Consensus Statements (1,2), the IIPs break down into the following categories: idiopathic pulmonary fibrosis (IPF) and its pathologic correlate usual interstitial pneumonia (UIP), nonspecific interstitial pneumonia (NSIP), acute interstitial pneumonia (AIP), cryptogenic organizing pneumonia (COP), lymphocytic interstitial pneumonia (LIP), desquamative interstitial pneumonia (DIP) and respiratory bronchiolitis interstitial lung disease (RBILD). The IIPs can present in either childhood or adulthood. However, the IIPs are much more common in the adult population. Of these IIPs, IPF is the most common and most severe form and has thus received the most attention in pulmonary research.

Clinically, patients with IPF typically present with shortness of breath and decreased exercise tolerance (3). PFT reveals restriction and radiographic imaging reveals interstitial fibrosis on chest roentgenogram and high-resolution computed tomography (HRCT) of the chest. Patients typically progress to hypoxemia and respiratory failure, with most patients dying from the disease within 5 years of diagnosis. Unfortunately, no effective treatments are available short of lung transplantation, a therapy with its own complications and feasible for only a small percentage of patients. The incidence of disease is approximately 20 per 100,000 males and 13 per 100,000 females (1), but rising. Most individuals present between ages 50 and 75, but patients can present outside this interval in either direction. Many individuals can be diagnosed with disease based on clinical presentation and classic findings on HRCT of the chest. When an individual does require a lung biopsy for diagnosis, a pathologic pattern referred to as UIP is noted (2).

While the cause remains unknown in IPF, over the past decade genetic discoveries in familial forms of disease have shown promise in helping the medical and scientific community gain significant insights into the pathogenesis of this disease.

### 61.2.2 Familial Interstitial Pneumonia (FIP)

Familial interstitial pneumonia (FIP) is defined when two or more individuals have an IIP within a single family (4–7). FIP has been described in the literature for over a century, but it has been the past decade that has greatly increased our understanding of this category of ILD, including some cases in which genetic links have been revealed (8–11). Studies from the United Kingdom and Finland suggested that familial forms of the disease account for approximately 2–4% of all cases of IPF (12,13). However, it is possible that this percentage may actually be higher (5,7). Studies from the United Kingdom and the Mayo Clinic in Minnesota suggest that adult patients who present with FIP are essentially indistinguishable from sporadic IPF patients in terms of clinical presentation, radiographic examination, histopathologic findings, and survival except that patients with FIP tended to present at an earlier age (6,12). Most families analyzed to date reveal that FIP is inherited in an autosomal dominant pattern (4,5,12). While penetrance of disease is clearly not 100%, it must be noted that this determination is greatly limited by the fact that patients typically present late in adulthood when other variables may lead to less frequent diagnoses.

In a recent collaborative study from the National Jewish Medical Center/Colorado University, Duke University, and Vanderbilt University, investigators reported the largest FIP cohort analyzed to date (111 families, 309 patients, 360 unaffected controls) (4). The results from this study revealed that male gender (55.7 vs. 37.2%,  $p < 0.0001$ ), older age (68.3 vs. 53.1 years,  $p < 0.0001$ ), and history of cigarette smoking (67.3 vs. 34.1%,  $p < 0.0001$ ) were risk factors for the presence of disease in these families. In this cohort, among individuals who had a biopsy performed, 85% were classified as IPF/UIP. However, interestingly, pathologic heterogeneity was observed within many individual families. While UIP was the only IIP pathology observed in 55% of families, the remaining 45% of families had two or more pathologic forms represented, with many families having both UIP and NSIP represented. These observations of pathologic heterogeneity within single families supported previous observations (8,9). Together, these studies suggest that, although described as different diseases based on pathologic description, these IIP disease categories may in fact have similar origins. Furthermore, the finding that cigarette smoking was a risk factor for the development of FIP suggests that environmental factors can influence the presentation of genetic-based familial ILD.

Among avenues to pursue genetic relationships in the IIPs, analyzing FIP cohorts are the most promising. Over the past decade, FIP families have been analyzed with candidate gene and linkage approaches with limited success. To date, four genes have been clearly linked to cases of adult FIP (surfactant protein C (SPC), surfactant protein A2, telomerase reverse transcriptase, and telomerase RNA component) in a causative manner, but together only account for approximately 15% of FIP cases (9–11,14). Pediatric ILD has been linked to genetic mutations in SPC and ATP-binding cassette transporter A3 (8,15). Newer generation genetic approaches such as whole exome sequencing (WES) and genome-wide association studies (GWAS) are now being employed, but results as yet are unknown. Genetic studies in FIP have been greatly limited by the fact that highly genetically informative families are rare in FIP, possibly because of decreased disease penetrance in some families, and also more likely because patients present late in life and blood or tissue specimens may not be available for those who are already deceased. While autosomal dominant inheritance suggests a single causative genetic defect for any given family, it is now clear that there is likely considerable locus heterogeneity in FIP, with many different individual genes across different families contributing to disease. However, despite these limitations, over the past decade genetic mutations have been linked to several cases of FIP as described later, and ongoing studies hold promise for further discoveries, all of which will improve our understanding of the pathogenesis of both familial and sporadic forms of this disease.

### 61.2.3 Surfactant Protein C Mutations and Pediatric ILD and Adult FIP/UIP

SPC is one of four surfactant proteins expressed in the alveolar space, with its prominent role being to maintain alveolar surface tension such that alveoli do not collapse. It is expressed throughout the lung epithelium during lung development, but in the mature lung is localized specifically to type II alveolar epithelial cells (AECs) (16). Over the past decade, some cases of both pediatric and adult ILD have been linked to genetic mutations in the SPC (*SFTPC*) gene. In 2001, Nogee and colleagues (8) made the initial report of *SFTPC* mutation-mediated ILD when they reported an infant with NSIP whose mother had previously been diagnosed with DIP in her first year of life. Genetic sequencing revealed a heterozygous G to A transition in the first base of intron 4 (IVS4+1 G to A) on a single allele in both child and mother, consistent with inheritance in an autosomal dominant pattern. This *SFTPC* mutation caused deletion of exon 4 and its 37 amino acids and is referred to in the literature as the *SFTPC*Δ<sup>exon4</sup> mutation. Mature SPC was not detected in the lung of either subject, but a misprocessed form of the pro-protein, pro-SPC, was noted in type II AECs. Following this initial study, *SFTPC* mutations have been

described in many cases of pediatric ILD, many of which are found in the carboxy-terminal region of pro-SPC (17–21).

After these reports linking *SFTPC* mutations to childhood ILD, questions arose as to whether disease occurred because of altered SPC function in the alveolar space or because of dysfunction in the type II AEC population including possible impairments in regenerative capacity (16). Shortly after the report by Nogee et al. (8), Amin and colleagues (22) reported a mother and two children who had chronic ILD and SPC deficiency (lack of mature SPC in the alveolar space), but no mutations in *SFTPC* (or surfactant protein B—*SFTPB*) were noted. Subsequently, studies have shown that mice deficient in SPC have a greater propensity to develop experimental lung fibrosis (23,24), suggesting that SPC deficiency may have a role in pulmonary fibrosis.

While *SFTPC* mutations may lead to altered expression of SPC in the alveolar space, multiple lines of evidence implicate aberrant intracellular processing of pro-SPC with type II AEC toxicity as the most likely result of these mutations (16,25). Transcription of the *SFTPC* gene and subsequent mRNA translation yield a 197 amino acid precursor protein (pro-SPC). The pro-SPC product is then processed through the endoplasmic reticulum (ER), Golgi, and distal secretory pathway, resulting in the mature 35 amino acid SPC protein that is secreted into the alveolar space. Carboxy-terminal *SFTPC* mutations lead to the production of a pro-SPC product that cannot be folded normally in the ER, leading to accumulation of protein, ER stress, activation of the unfolded protein response (UPR), and type II AEC injury (26–28).

Following the identification of *SFTPC* mutations linked to childhood cases of ILD, investigators evaluated whether or not similar mutations might explain cases of adult FIP. In 2002, Thomas and colleagues (9) reported a family in which 11 adults had ILD (six with biopsy-confirmed UIP/IPF and five with IPF on clinical grounds) and three children had NSIP. In this large family, a heterozygous exon 5 +128 T to A transversion leads to the substitution of glutamine for leucine at amino acid position 188 (L188Q) of pro-SPC. Immunostaining for pro-SPC on lung tissue sections from affected individuals revealed an abnormal staining pattern, while accumulation of atypical intracytoplasmic vesicles was noted in type II AECs on electron microscopy. Mouse lung epithelial (MLE) cells expressing the mutant L188Q *SFTPC* were also noted to have similar intracytoplasmic vesicles, suggesting aberrancy in SPC processing. Subsequently, in vitro studies revealed that this L188Q *SFTPC* mutation results in a pro-SPC product that cannot be folded properly, leading to ER stress and caspase pathway activation (28,29). Subsequent to this initial study by Thomas and colleagues, other *SFTPC* mutations have been found in adult FIP cohorts, including a recent study by Van Moersel and colleagues (30) in which *SFTPC* mutations

represented approximately 25% of FIP cases in a Dutch cohort, a percentage higher than what has been observed in other cohorts.

While detected in FIP cases, mutations in *SFTPC* are rarely encountered in sporadic cases of IPF. In 2004, Lawson and colleagues (31) reported a study of 89 patients with UIP, 46 patients with NSIP, and 104 normal subjects and found only one mutation that resulted in an amino acid sequence change in pro-SPC. In this individual, a genetic mutation in exon 3 caused a substitution of threonine to isoleucine at amino acid 73 (I73T). This I73T mutation is likely the most common of the *SFTPC* mutations reported to date, occurring in both pediatric cases of ILD (17–21) and adult cases of FIP (30).

Although rarely found in IPF, the fact that mutations in *SFTPC* can lead to biopsy-proven UIP points to the type II AEC as the critical cell in the pathogenesis of this disease. One question that arose as a result of the genetic studies was whether or not pathways important in *SFTPC* mutation-mediated disease might also be important in sporadic cases of IPF. In 2008, two separate groups of investigators reported studies that suggested a role for AEC ER stress in non-*SFTPC* mutation-associated ILD (29,32). Lawson and colleagues (29) found that ER stress markers were prominent in AECs lining areas of fibrosis in lung biopsies from individuals with non-*SFTPC* mutation-associated FIP as well as from individuals with sporadic IPF. Soon thereafter, Korfei and colleagues (32) reported a cohort of sporadic IPF/UIP lung biopsies with similar findings of AEC ER stress, but also demonstrated that caspase pathway activation was present in these same AECs. Together, these two studies demonstrated that ER stress pathways may be important not only in the pathogenesis of *SFTPC* mutation-associated disease, but in sporadic cases of IPF as well.

#### 61.2.4 Surfactant Protein A2 Mutations and Adult FIP

Considering that *SFTPC* mutations were found in cases of FIP, suspicion arose on whether or not mutations in the genes for the other surfactant proteins might be found in other cases of FIP. In 2009, Wang and colleagues (14) reported such a finding related to *SFTPA2*, one of two genes that encode for surfactant protein A. In that study, they analyzed a highly genetically informative family in which 15 affected individuals had FIP and/or lung adenocarcinoma with bronchoalveolar cell carcinoma features. Starting with a whole genome linkage analysis, they found a 15.7Mb region on chromosome 10 that segregated with disease. This region contains both *SFTPA1* and *SFTPA2*, as well as *SFTPD*, the gene for surfactant protein D. Sequencing of all three of these candidates was performed, and from this a heterozygous mutation in *SFTPA2* was found. A G to T transversion in codon 231 was noted, which predicted a substitution of valine for glycine at the highly conserved amino acid

position 231 (G231V). Subsequently, 58 additional families were analyzed, with one family having a different *SFTPA2* mutation, a T to C transversion that resulted in the substitution of serine for phenylalanine at amino acid position 198 (F198S). Both these mutations (G231V and F198S) are in the protein's carbohydrate recognition domain. Subsequent in vitro analyses by these investigators demonstrated that these mutations result in a protein product that is retained in the ER, leading to ER stress (14,33), raising further questions on the roles that aberrant protein processing and ER stress in type AECs play in the pathogenesis of IPF.

### 61.2.5 *ABCA3* Gene Mutations in Pediatric ILD

ATP-binding cassette transporter A3 (*ABCA3*) is expressed in the lamellar bodies of type II AECs, suggesting an important role for this protein in surfactant processing. In 2004, Shulenin and colleagues (34) reported a study in which they analyzed 21 infants with severe neonatal surfactant deficiency in whom the etiology for their deficiency was unknown, observing that 16 of the 21 individuals (76%) had mutations in the *ABCA3* gene. These patients were either homozygous for the same mutation, or compound heterozygous for different mutations. Analysis of lung tissue sections, which were available from a subset of patients, by light and electron microscopy revealed markedly abnormal lamellar bodies. Taken together, these studies reveal that *ABCA3* is critical for surfactant processing and the proper formation of lamellar bodies.

After this report on *ABCA3* mutations and neonatal surfactant deficiency, Bullard and colleagues (15) evaluated a large cohort of children with pediatric ILD for mutations in *ABCA3*. From a cohort of 165 subjects who were known to not have mutations in *SFTPC* or *SFTPB*, four patients with a diagnosis of DIP who were over 10 years of age were selected for genetic sequencing of the 30 coding exons of *ABCA3*. Three of the four patients were compound heterozygotes for mutations in *ABCA3*, with each of these three individuals carrying one copy of a specific mutation, E292V, which had been described previously (34). Screening of an additional 153 subjects from the cohort was then performed for this specific mutation with an additional seven subjects identified as being E292V *ABCA3* mutation carriers. Of these seven additional patients, five had a second *ABCA3* mutation, while two did not. Thus, of the 165 subjects in the cohort, a total of 10 carried the E292V mutation, eight of whom were compound heterozygotes for *ABCA3* mutations (15). However, this analysis did not evaluate the possibility that other children in the cohort could have had different *ABCA3* mutations. Subsequently, Young and colleagues (35) reported a teenage boy who had ILD with a biopsy pattern of UIP and an *ABCA3* mutation. Otherwise, to date, studies in the adult population have

yet to clearly link *ABCA3* mutations to adult cases of FIP (30).

### 61.2.6 *ABCA3* Mutations May Modify Clinical Expression of *SFTPC* Mutations

To determine if *ABCA3* mutations might have a disease-modifying effect on *SFTPC* mutations, Bullard and Nogee (36) evaluated four infants with pediatric ILD who had the I73T *SFTPC* mutation and noted that three had concomitant heterozygous mutations in *ABCA3*. In all cases, all parents were asymptomatic from a respiratory standpoint. Pedigree analysis indicated that each child had inherited the *SFTPC* mutation from one parent and the *ABCA3* mutation from the other. Taken together, the fact that both parents were disease free, yet the child had prominent childhood ILD raised suspicion that heterozygous *ABCA3* mutations may modify the effect of the *SFTPC* mutation, leading to the development of clinical ILD. Following this pediatric study, Crossno and colleagues (37) reported a small adult FIP family in which the I73T *SFTPC* mutation was found in conjunction with a heterozygous *ABCA3* variation, although given the small pedigree it is not clear to what role this *ABCA3* variant played in the presentation of ILD.

### 61.2.7 Telomerase Mutations in FIP/UIP

Multiple genetic diseases can include manifestations of pulmonary fibrosis, including dyskeratosis congenita (DKC) (4,5,38). DKC is discussed later in this chapter, but warrants a brief introduction here because observations in this disease led to important discoveries related to telomerase mutations in FIP. DKC was originally described based on a triad of abnormal skin pigmentation, nail dystrophy, and oral leukoplakia, but actually involves many different organ systems (38). Among these, the lungs are frequently affected, with 20% of DKC individuals having pulmonary fibrosis. In fact, behind aplastic anemia, respiratory failure is the second most frequent cause of death in DKC subjects (39). Genetic mutations in *DKC1*, the gene encoding for dyskerin, are responsible for the X-linked form of DKC (40,41). Some autosomal dominant forms of DKC have been linked to genetic mutations in telomerase reverse transcriptase (*TERT*) and telomerase RNA component (*TERC*) (42–44). These components are essential for the normal operation of the telomerase complex to maintain telomere integrity, and multiple lines of evidence suggest that it is telomere shortening that leads to disease manifestations when these mutations are present.

In 2005, Armanios and colleagues (44) reported a *TERT* mutation in a DKC family in which pulmonary fibrosis was a predominant finding. This led the investigator to question whether or not FIP cases might also be linked to mutations in components of the telomerase complex, and indeed that proved to be the case. In 2007,

Armanios and colleagues analyzed 73 FIP families and found that five of these families had genetic mutations in *TERT* and one family had a mutation in *TERC* (10). Of the six probands from these families, five had lung biopsies consistent with UIP, while one had a biopsy that read as IIP. Across the six families, 19 individuals were affected by FIP. Classic mucocutaneous manifestations of DKC were not present in any affected subjects. Mutation carriers without lung disease were noted, but they tended to be younger than their affected relatives. In vitro studies of the identified mutations demonstrated decreased telomerase activity. Furthermore, telomere shortening in peripheral blood lymphocytes was prominently noted in the mutation carriers compared to nonmutation carriers. In fact, all mutation carriers had average telomere lengths that were at or below the 10th percentile when compared to age-based telomere length distribution curves.

Shortly after this initial report, Tsakiri and colleagues (11) reported similar findings in another FIP cohort. While the Armanios study relied on a candidate gene approach, the Tsakiri study utilized two highly genetically informative families to link to a region on chromosome 5. At that point, *TERT* was selected as a potential candidate and two separate mutations in the two families were discovered. Subsequently, an additional 44 FIP families were analyzed, with four having heterozygous *TERT* mutations and one a heterozygous *TERC* mutation. As in the Armanios study, in vitro evaluations of the mutations revealed decreased telomerase activity. Furthermore, on peripheral blood leukocytes, telomere lengths were shorter in mutation carriers compared to age-matched noncarriers. In addition, the investigators also analyzed an additional 44 cases of sporadic ILD and identified a single subject with a mutation in *TERT*. When considered together, these two studies suggest that telomerase mutations are the underlying cause of disease in approximately 10% of FIP.

A year following their genetic studies, both the aforementioned groups reported that telomere shortening was prominent in individuals with pulmonary fibrosis even without defined mutations in *TERC* or *TERT* (45,46). In the first report, Cronkhite and colleagues (45) analyzed a cohort of pulmonary fibrosis patients who did not have mutations in *TERT* and *TERC*, including probands from 59 different FIP families and 73 subjects with sporadic IPF. In this study, the investigators found that 24% of the FIP subjects and 23% of the sporadic IPF subjects had peripheral blood leukocyte telomere lengths that were below the 10th percentile compared to controls. Subsequently, Alder and colleagues (46) analyzed 100 cases of sporadic IPF and found one subject with a mutation in *TERC* (none found in *TERT*). Among these individuals, 62 had telomere length measurements on peripheral blood lymphocytes available, with 60 of the 62 (97%) having telomere lengths less than the median of healthy controls and six of 62 (10%) with telomere lengths less than the first percentile compared to healthy controls.

Furthermore, using fluorescent in situ hybridization techniques, these investigators also demonstrated that AECs in these individuals also had telomere shortening. Taken together, these two studies suggest a potentially critical role for telomere shortening in the pathogenesis of IPF, even when defined telomerase mutations are not present.

Building on the genetic observations by Armanios and colleagues and Tsakiri and colleagues mentioned earlier, in 2008, researchers from Japan analyzed a cohort of patients with IPF and controls with GWAS and identified an association of a common *TERT* variant with susceptibility to IPF (47). This A to C SNP was in intron 2 of *TERT* (rs2736100). Among 242 IPF cases and 1469 controls, the minor allele frequency in diseased individuals was 0.277 compared to 0.409 in controls ( $p = 2.9 \times 10^{-8}$ ), thus indicating that the more common A was the risk allele in this cohort.

### 61.2.8 *ELMOD2* Linkage in FIP Cases in Finland

In 2002, Hodgson and colleagues (13) reported 17 multiplex FIP families in Finland. In this evaluation, familial clustering was described, including the likelihood of a distant shared ancestor. Subsequently, they evaluated six of these families using a genomewide scan approach, identifying five potential loci on chromosomes 3, 4, 9, 12, and 13 (48). When hierarchical mapping was performed on 24 families, a shared haplotype on chromosome 4q31 emerged in eight of the 24 families. Compared to population controls, this haplotype was significantly more frequent in affected individuals (odds ratio (OR), 6.3; 95% confidence interval (CI) 2.5–15.9;  $p < 0.0001$ ). The shared haplotype region encompassed a gene known as *LOC152586* and the first three exons of a gene known as *ELMOD2*. The function of neither gene is known, but gene expression evaluation suggested expression of *LOC152586* in the testis and not in the lung. In contrast, *ELMOD2* was expressed in both alveolar macrophages and AECs in normal lung, but not detected in IPF/UIP lung biopsies. Real-time polymerase chain reaction (PCR) studies of mRNA expression from frozen lung tissue revealed that *ELMOD2* expression was markedly decreased in IPF/UIP lung compared to normal lung. However, sequencing of *ELMOD2*'s nine exons and exon–intron boundaries in affected individuals from the linked families did not reveal any genetic mutations. Despite this observation, however, given the strength of the shared haplotype, *ELMOD2* remains a candidate gene for further evaluation in FIP.

### 61.2.9 Genetic Polymorphism Associations in IIP

Common polymorphisms in multiple genes have been analyzed for potential associations with IPF. However, all these studies have been in small cohorts, and in many

instances the results have never been confirmed in other populations. A brief summary of some of these studies is described below.

**61.2.9.1 Interleukin-1 Receptor Antagonist and Tumor Necrosis Factor- $\alpha$ .** Interleukin-1 $\alpha$  (IL-1 $\alpha$ ) and IL-1 $\beta$  are key proinflammatory cytokines and bind to the IL-1 receptor to initiate a proinflammatory response. However, when bound to the IL-1 receptor antagonist (IL-1RN), no response is elicited, with this system acting as a downregulation mechanism. Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) is another prominent proinflammatory cytokine. IL-1RN+2018 and TNF- $\alpha$ -308 polymorphisms have both been implicated in inflammatory diseases. In 2000, Whyte and colleagues (49) observed an association with IPF with the IL-1RN+2018C>T polymorphism in a cohort of English and Italian patients. However, two subsequent studies analyzed an *IL-1RN* intron variable number tandem repeat that is in strong linkage disequilibrium with the +2018C>T polymorphism and found no association with IPF (50,51). The TNF- $\alpha$ -308G>A allele was found to be associated with IPF in the cohort of English and Italian patients (49). The study by Riha and colleagues (51) confirmed this finding in an Australian cohort, but a later study by Pantelidis and colleagues (52) did not find an association with the TNF- $\alpha$ -308G>A allele.

**61.2.9.2 Surfactant Proteins.** Because of their expression in the lung, the genes for surfactant proteins are attractive targets for evaluating for disease risk-associated polymorphisms. In 2003, Selman and colleagues (53) analyzed an IPF cohort for common polymorphisms in the four surfactant protein genes (*SFTPA1*, *SFTPA2*, *SFTPB*, *SFTPC*, *SFTPD*) but found no associations with IPF. However, in subgroup analysis, the *SFTPA1*\_6A4 allele was found to be associated with increased IPF risk in nonsmoking subjects, while the *SFTPB* B1580\_C allele was associated with increased IPF risk in smokers. This *SFTPB* allele has previously been reported as having a higher risk for chronic obstructive pulmonary disease (COPD), a smoking-related lung disease (54). *SFTPC* has two common polymorphisms (T138N in exon 4 of pro-SPC and S186N in exon 5), but there is no clear evidence that either affects SPC processing or function. In a study from Finland of infants with respiratory distress syndrome, the asparagine allele at position 186 was found in greater frequency in affected individuals compared to controls ( $p=0.040$ ). In the same study, the asparagine allele at position 138 approached statistical significance for increased frequency in affected individuals ( $p=0.071$ ) (55). In contrast, in a study from Japan of 41 subjects with FIP or sporadic IIP, the serine allele at position 186 was found in greater frequency in affected individuals compared to controls (56). However, other studies have failed to identify any association between either the T138N or S186N *SFTPC* polymorphisms, including the Selman study (53) and another study by Markart and colleagues (57).

**61.2.9.3 Angiotensin II Pathways.** Angiotensin converting enzyme (ACE) converts angiotensin I to II. Blocking the actions of angiotensin II, either through ACE inhibitors or angiotensin II type 1 receptor blockers, attenuates lung fibrosis in mouse models (58,59). Serum ACE levels are affected by an ACE insertion/deletion polymorphism in intron 16. In a 2001 study of 24 patients with either UIP or fibrotic NSIP, Morrison and colleagues (60) found that the D allele frequency was greater in affected subjects compared to controls (69 vs. 54%;  $p=0.04$ ). In 2008, Molina and colleagues (61) reported that the G-6A polymorphism in the promoter of the gene (*AGT*) encoding angiotensinogen, the precursor for angiotensin II, did not predispose individuals to develop IPF, but was associated with disease progression over time, with worse oxygenation in IPF subjects carrying the G genotype.

**61.2.9.4 Transforming Growth Factor- $\beta$ 1.** Transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1) is one of the principal profibrotic cytokines, with multiple lines of evidence revealing a prominent role in the pathogenesis of lung fibrosis. Polymorphisms at codons 10 (L10P caused by a position 869T>C substitution) and 25 (R25P caused by a 915G>C substitution) appear to affect the level of TGF- $\beta$ 1 produced. The codon 915C>C polymorphism affecting codon 25 has been reported to be associated with post-lung transplant allograft fibrosis (62). The CC genotype of the codon 10 869T>C polymorphism is associated with worse lung disease in cystic fibrosis (63). Neither the codon 10 nor the codon 25 polymorphisms have been associated with IPF. However, in a study by Xaubet and colleagues (64), the L10P change was associated with progression of gas exchange abnormalities in those individuals with IPF.

**61.2.9.5 Complement Receptor 1.** A common polymorphism in exon 33 (5507C>G) of the gene for erythrocyte complement receptor 1 (*CR1*) affects the level of CR1 expressed per erythrocyte. In 2002, Zorzetto and colleagues (65) reported that the homozygous GG allele was associated with sarcoidosis. This group subsequently analyzed a group of IPF patients and noted that the GG genotype was more commonly represented in IPF subjects than in controls (66). However, a second study analyzing two separate cohorts of patients found no association with this *CR1* polymorphism and IPF (67). Furthermore, another study did not identify an association with this *CR1* polymorphism and sarcoidosis (68).

**61.2.9.6 Other Candidate Genes Evaluated.** Other polymorphism evaluations have been performed in IPF (69). Human leukocyte antigen (HLA) associations with IPF have been reported including HLA-Dw6, HLA-DR2, HLA-B8, HLA-B12, and HLA-B15 (70–73). The plasminogen activator inhibitor-1 (*PAI-1*) promoter polymorphism 4G/5G has been reported to be associated with increased risk of NSIP, but not UIP (74). In 2001, Pantelidis and colleagues (52) reported that while polymorphisms in IL-6 (intron 4G) and TNF receptor II (1690C) were not individually associated with IPF, the

combination of both alleles was associated with greater risk of disease. Two different matrix metalloproteinase promoter polymorphisms were analyzed by Checa and colleagues (75), with the -1607 polymorphism being associated with risk for IPF in general and the -755 polymorphism conferring IPF risk in individuals that smoke. In a study by Xaubet and colleagues (76), the carriage of double homozygous alleles with two separate cyclooxygenase-2 polymorphisms conferred a mild increased risk for IPF. In 2009, Aquino-Galvez and colleagues (77) reported an association with IPF and a polymorphism in the major histocompatibility complex (MHC) class 1 chain-related gene A. Two separate studies by Bournazos and colleagues (78) analyzed Fcγ receptor (FcγR) polymorphisms in IPF cohorts, noting that an FcγR IIIb polymorphism was associated with IPF risk, while an FcγRIIa polymorphism was associated with the severity of IPF, but not the presence of IPF (79). Specific polymorphisms in many other selected genes have been analyzed with no evidence of association with IPF (69). However, it is likely that many other gene candidates have been analyzed in IPF cohorts, but have never been reported because of the difficulties with publishing negative results.

### 61.3 ASSOCIATED POLYMORPHISMS IN OTHER COMMON FORMS OF ILD

#### 61.3.1 Systemic Sclerosis-Related ILD

In many of the rheumatologic disorders, ILD may develop and even be a prominent finding. Of these, systemic sclerosis, or scleroderma is best described in association with pulmonary fibrosis. Systemic sclerosis is characterized by excessive deposition of connective tissue components including collagen in the skin and other tissues, prominent alterations in the microvasculature, and abnormalities in cellular and humoral immunology. Among those tissues that can be affected, the lung is sometimes involved with significant pulmonary fibrosis, and affected patients typically present with respiratory symptoms similar to those of individuals with IIP. When lung biopsy is performed, NSIP is a commonly encountered histological pattern, although UIP is also observed (80). Over 90% of patients with systemic sclerosis have detectable antinuclear antibodies in the serum. Three predominant antibodies are observed: (1) anti-RNA polymerase antibodies, (2) anti-centromere antibodies, and (3) antitopoisomerase antibodies (ATAs), each consistent with clinical disease subsets with ATA (also known as anti-Scl-70) strongly associated with lung fibrosis (81,82).

Since it is thought that pathogenesis of systemic sclerosis involves a T-cell-mediated response to an antigen, early genetic studies evaluated the MHC on chromosome 6. In 2001, Gilchrist and colleagues (81) reported that 39 of 54 (72%) ATA-positive patients carried an HLA-DRB1\*11 allele in comparison to 18% of controls ( $p=0.00006$ ). Although not as strong, they also found

an association with another allele, HLA-DPB1\*1301. A separate study found similar associations with HLA-DRB1\*11, specifically finding that the allelic subtype \*1104 was associated with the presence of ATAs and lung fibrosis (83). Other genes have been analyzed as well using a candidate gene approach. In a study by Sato and colleagues (84), TNF alleles were not associated with lung fibrosis, but the TNF -863A allele was strong associated with anticentromere antibodies, which are seen less often in pulmonary fibrosis compared to ATAs. Weak associations with lung fibrosis have been found with both secreted protein acidic and rich in cysteine/osteonectin (SPARC) and fibronectin 1 (FN1) (85,86). Two haplotypes (Hap-5 and Hap-6) in the fibrillin 1 gene (FBN1) have been associated with systemic sclerosis, with Hap-5 specifically associated with pulmonary fibrosis (87). Two separate studies detailed an association between the TGF-β L10P codon and lung fibrosis in systemic sclerosis (88,89). In a study by Beretta and colleagues (90), 104 subjects with systemic sclerosis were followed over time, with 25 (12.3%) of these individuals developing severe lung fibrosis. In this cohort, the interleukin-1β (IL-1β) C+3962T polymorphism was found to be associated with the presence of severe restrictive lung disease ( $p=0.003$  for TT versus CC; hazard ratio, 6.61; 95% CI, 2.28–19.15).

#### 61.3.2 Sarcoidosis

Sarcoidosis is a multisystem disorder in which granulomas form and accumulate in the tissues. This process can occur in any organ, but over 90% of individuals present with pulmonary findings, ocular involvement, and/or skin manifestations (91). Pulmonary presentations range from incidental detection of hilar adenopathy on chest radiograph in asymptomatic subjects to chronic respiratory failure due to severe parenchymal lung fibrosis. Given the fact that the granuloma is the central pathologic finding in sarcoidosis, a significant aspect of research into the pathogenesis of this disease has targeted searches for an inciting antigen or pathogen (91).

Familial clustering of cases of sarcoidosis could potentially occur because of either genetic disposition or because most families share similar environmental exposures. A Case-Control Etiologic Sarcoidosis Study (ACCESS), the most comprehensive evaluation of familial sarcoidosis, analyzed 706 case-control pairs, with the study revealing that relatives of individuals with sarcoidosis had a much greater likelihood of having sarcoidosis compared to relatives of controls (OR, 5.8; 95% CI, 2.1–15.9 for siblings; OR, 3.8; 95% CI, 1.2–11.3 for parents) (92). Because of important immunologic features of sarcoidosis, HLA alleles have been analyzed with class I HLA-B8 (93) and class II HLA-DRB1 and DQB1 found in association with sarcoidosis (94,95).

Genome-wide linkage approaches have had some success in identifying genetic associations with sarcoidosis.

In the Sarcoidosis Genetic Analysis Consortium (SAGA) study, an analysis of African-American families with sarcoidosis, 15 potential associations (as based on  $p \leq 0.05$ ) were identified, with the most prominent of these being on chromosome 5q11 ( $p = 0.0005$ ) (96,97). Following these initial SAGA findings, fine mapping in African-American families not only further refined this disease susceptibility association to 5q11.2 but also noted a protective association with genes on chromosome 5p15.2 (98). In a separate and earlier genome-wide linkage study, an analysis of 63 German sarcoidosis families suggested linkage to chromosome 6p21 (and five other potential associations) (99). Following this observation, Valentonyte and colleagues (100) performed fine mapping of the 6p21 region and observed an association between sarcoidosis and a polymorphism in the butyrophilin-like2 gene (*BTNL2*). Subsequently, a disease-associated truncating splice site mutation in this gene, r22076530, was described. This association between sarcoidosis and *BTNL2* has since been confirmed in studies of other populations (96,98,101,102). A member of the B7 family (which includes CD80 (B7.1) and CD86 (B7.2)), *BTNL2* is thought to act as a negative costimulatory molecule (101), although its exact function remains largely unknown (91).

### 61.3.3 Hypersensitivity Pneumonitis and Chronic Beryllium Disease

Hypersensitivity pneumonitis encompasses a group of lung diseases characterized by both inflammation and fibrosis that results from a broad range of specific environmental exposures. Both acute and chronic forms exist, with lung fibrosis potentially progressing to end-stage lung disease with prolonged exposure to some of the offending agents. HLA associations have been reported with pigeon breeder's lung, one of the more commonly encountered forms of hypersensitivity pneumonitis, including HLA-DR7 (103), HLA-DRB1\*1305, and HLA-DQB1\*0501 (104). An association with the TNF allele TNF-2(-)(308) has also been described (104).

Exposure to beryllium can lead to prominent ILD. Among those individuals who have the appropriate level of exposure to beryllium, the HLA-DPB1 Glu69 polymorphism has been associated with a 10-fold greater risk of developing lung disease (105).

## 61.4 GENETIC SYNDROMES WITH ILD MANIFESTATIONS

Several Mendelian disorders can have prominent pulmonary involvement including manifestations of ILD. Some of these relevant disorders have been selected for discussion in this section of the chapter. Considering that many of these are covered in other sections of this text, these diseases with their associated ILD manifestations are presented in a brief format.

### 61.4.1 Dyskeratosis Congenita

DKC, mentioned previously in this chapter in the section related to telomerase mutations and FIP, is a rare hereditary disorder initially described based on a triad of mucocutaneous manifestations—oral leukoplakia, nail dystrophy, and abnormal pigmentation of the skin. However, it is actually a multisystem disorder with the potential to have manifestations in tissue sites that require ongoing cellular turnover. Among the classic mucocutaneous features, 78% of DKC patients have oral leukoplakia, 88% have nail dystrophy, and 89% have abnormal skin pigmentation, based on DKC registry estimates. Bone marrow failure occurs in approximately 86% of DKC patients and is the leading cause of death. Pulmonary fibrosis occurs in approximately 20% of DKC patients and is the second leading cause of death. In individuals with pulmonary fibrosis, clinical presentations are similar to those of individuals with IIP, and when lung biopsies are performed, the histologic pattern of UIP is commonly observed. Additional possible DKC manifestations include short stature, learning difficulties, dental disease, liver disease, epiphora, esophageal strictures, and increased malignancy risk (38).

On evaluation of the DKC registry in 2006, over half of the individuals had not yet had a disease causative genetic mutation described (38). However, mutations in genes that encode for proteins in the telomerase complex have been linked to DKC. The X-linked form of the disease was mapped to chromosome Xq28 (40,106), with the subsequent identification of mutations in *DKC1*, the gene encoding for the protein dyskerin (41). Dyskerin is expressed in all tissues, is known to be involved in ribosome production, and serves an important role in the telomerase complex. Ultimately, genetic mutations in *DKC1* are found in approximately 33% of DKC registry cases (38). DKC also can present in autosomal dominant forms, with some cases linked to heterozygous mutations in telomerase reverse transcriptase (*TERT*) (44) and the telomerase RNA component (*TERC*) (42,43). In addition, heterozygous mutations in *TINF2*, a gene that encodes one of the proteins in the shelterin complex that protects telomeres, have been reported (107,108). Patients with autosomal recessive DKC have mutations in *TERT* (109) as well as two other genes encoding proteins in the telomerase complex—*NOP10* (110) and *NHP2* (111). Telomere shortening occurs with mutations in *DKC*, *TERT*, *TERC*, *TINF2*, *NOP10*, and *NHP2*. Multiple lines of evidence, including mouse model work, suggest that DKC manifestations are related to the progressive telomere shortening that occurs because of decreased telomerase activity associated with the mutations (112–116). In contrast, a recent report linked cases of DKC to autosomal recessive mutations in the gene *C16orf57*, but telomere lengths in affected subjects were normal (117). Pulmonary fibrosis has been noted in DKC cases caused by *DKC*, *TERT*, and *TERC* mutations, but to

date information is limited on the prominence of pulmonary fibrosis in DKC cases caused by *TINF2*, *NOP10*, *NHP2*, or *C16orf57* mutations.

### 61.4.2 Hermansky-Pudlak Syndrome

Hermansky-Pudlak syndrome (HPS) is a group of heterogeneous autosomal recessive disorders. Eight different subtypes have been described, each with a different responsible gene. For each human form of *HPS*, a similar murine gene defect has been described; however, seven additional *HPS* genes in mice occur (118). All eight human subtypes have the clinical findings of oculocutaneous albinism and prolonged bleeding from defective platelet function. HPS is classically diagnosed when an individual with albinism and easy bruising is evaluated and an absence of platelet dense granules is noted on electron microscopy. Other manifestations of disease can be present and depend on the given subtype. Multiple lines of investigation suggest that *HPS* genetic mutations result in aberrancies in protein trafficking with dysfunction of lysosome-related organelles (118–120). *HPS* genes appear to be expressed ubiquitously, but gene defects appear to affect specific cell populations, including melanocytes and pigment epithelial cells, neutrophils, and platelets. In the case of those subtypes that result in ILD, the cell of interest appears to be the type II AEC.

For most of the *HPS* genes, the function of the encoded protein remains unknown, although most have regions that predict association with other proteins (121,122). HPS is the most commonly encountered genetic disease in Puerto Rico, with 1/1800 individuals in northwest Puerto Rico affected (123). HPS-1 is the most common subtype, accounting for approximately 50% of HPS cases outside the Puerto Rican population. Over 20 disease-causing mutations have been reported in *HPS1* (118), located on chromosome 10q23.1-23.3 (124). HPS-2 is caused by mutations in *AP3B* (125). *HPS3* is on chromosome 3q24 (126), *HPS4* on chromosome 22q11.2-q12.2 (127), *HPS5* on chromosome 11p14 (128), *HPS6* on chromosome 10q24.32 (128), *DTNBP1*, the gene for HPS-7 on chromosome 6p22.3 (129), and *BLOC1S3*, the gene for HPS-8, on chromosome 19q13 (130).

Among the eight different subtypes, pulmonary fibrosis occurs in HPS-1 and HPS-4. The proteins encoded by *HPS1* and *HPS4* function together in the BLOC-3 protein complex (131,132). In the lung of individuals with HPS-1 or HPS-4, the lamellar body, a lysosomal-related organelle, of type II AECs appears to be affected with subsequent aberrancies in trafficking of an as yet unidentified protein (118). In most individuals with HPS-1 and HPS-4 who survive to adulthood, ILD can be found, with many patients having severe pulmonary fibrosis that progresses to respiratory failure (133,134). Individuals who present with lung fibrosis have an average age of onset of symptoms of 35 and an average age of death related to respiratory failure of 37. Clinical

presentations for HPS-1- and HPS-4-related pulmonary fibrosis mirror that seen with the IIPs. In those individuals who have a lung biopsy performed, a pathologic pattern similar to UIP is often observed. Interestingly, hyperplastic AECs filled with phospholipid-rich droplets and enlarged lamellar bodies are frequently prominent on these biopsies, an observation that points to possible defects in the secretory pathway (135). Compared to HPS-1, HPS-4 is much less frequently encountered, but lung manifestations occur in the same pattern as noted in HPS-1 (127,136), a finding likely related to the fact that they are involved in the same BLOC-3 protein complex.

### 61.4.3 Lymphangioleiomyomatosis and Tuberous Sclerosis Complex

Lymphangioleiomyomatosis (LAM) is characterized by diffuse infiltration of benign smooth muscle-like cells in the lung parenchyma with resultant progressive cyst formation (137). In pulmonary clinics, the most commonly encountered form falls into the category of “sporadic”-LAM, or S-LAM. Patients typically present with chronic dyspnea on exertion and can have chest X-rays that suggest an interstitial pattern, but computed tomography reveals the burden of lung cysts. Patients can present with patterns of obstruction and/or restriction on PFT. Spontaneous pneumothoraces are also common. The sporadic form of LAM occurs exclusively in women. Pulmonary manifestations of LAM are also encountered in the genetic disease tuberous sclerosis complex (TSC), and in reality, TSC with LAM (TSC-LAM) is more common, although many of these TSC individuals never present with respiratory symptoms.

TSC is an autosomal dominant tumor suppressor syndrome, with individuals carrying a heterozygous mutation in one copy of an allele and disease manifestations occurring when the second allele is lost through somatic mutation (138). TSC is caused by mutations in one of two different genes that encode for proteins that function together. *TSC1* is on chromosome 9q34, encoding for hamartin, and *TSC2* is on chromosome 16p13.3, encoding for tuberin (139–141). Hamartin and tuberin interact in the cell and are involved in regulating cellular growth and proliferation (142). Over 600 mutations have been reported in these two genes (143–145). TSC is characterized by hamartomas and dysplasias in multiple organs, including abdominal angiomyolipomas (AMLs) of the kidney, liver, or spleen, retinal hamartomas, and skin angiofibromas. In addition, the central nervous system (CNS) is frequently affected by subependymal nodules, giant cell astrocytomas, and cortical tubers (138). LAM can frequently occur, but the degree of respiratory compromise is quite variable among patients. In addition, multifocal micronodular pneumocyte hyperplasia (MMPH), a nodular proliferation of type II AECs, can be found in some TSC cases (146). With S-LAM, affected individuals not only predominantly present with severe

respiratory symptoms but may also have AMLs of the kidneys, lymphangiomyomas, and axial thoracic and abdominal adenopathy. However, the other manifestations of TSC, such as CNS involvement, are not found.

Similarities between S-LAM and TSC-LAM suggested that aberrancies in *TSC1* or *TSC2* might underlie the sporadic form as well. In 1998, two groups of investigators analyzed tissue from AMLs and lymph nodes from S-LAM patients and found loss of heterozygosity for *TSC2* with no *TSC2* mutations noted in peripheral blood leukocytes (147,148). Following this breakthrough, Carsillo and colleagues (149) analyzed S-LAM lesions from lung and kidney and found *TSC2* missense and truncating mutations in the affected tissues, while normal tissue surrounding the lesions as well as peripheral blood leukocytes had no *TSC2* mutations. These results suggested that diseased tissues were affected by the occurrence of two somatic *TSC2* mutations, and in fact it is now thought that most cases of S-LAM are caused in this manner.

#### 61.4.4 Pulmonary Langerhan Cell Histiocytosis

Pulmonary Langerhan cell histiocytosis (PLCH) is a lung disorder, most frequently encountered in smokers, in which cells of dendritic lineage (referred to as Langerhan cells) proliferate in the lung parenchyma leading to prominent pulmonary manifestations (150,151). Most individuals present with complaints of dyspnea on exertion and cough, and as with LAM, spontaneous pneumothorax is a common occurrence. Radiographic findings depend on the extent of disease, with initial chest radiographics and computed tomography potentially revealing a micronodular or reticular appearance. However, with disease progression, cystic lung disease becomes prominent and can lead to severe end-stage lung destruction. Multiple lines of evidence point to PLCH being caused by cigarette smoke, and in fact, some patients will dramatically improve with smoking cessation. Familial cases have been described, but no clear genetic association is known. One study suggested an association with the TNF $\alpha$ -308 promoter allele (152), but such an association was not observed in a subsequent study (153). However, this second study did suggest an increased frequency of HLA Cw7 and DR4 in PLCH (153).

#### 61.4.5 Pulmonary Alveolar Proteinosis

Pulmonary alveolar proteinosis (PAP) is a rare lung disease in which surfactant-rich lipoproteinaceous material accumulates within the alveolar space (154). The acquired or idiopathic form of PAP is the most common, but secondary and congenital forms occur as well. Patients with idiopathic PAP typically have clinical symptoms of progressive dyspnea and cough with a chest radiograph

that suggests an alveolar filling process. Computed tomography reveals a pattern of ground glass opacification with intralobular and interlobular septal thickening. Bronchoalveolar lavage yields a milky opaque fluid rich in surfactant, while lung biopsy reveals eosinophilic material in the airspaces, but with relatively preserved alveolar architecture. For many years, whole-lung lavage remained the main therapeutic approach (154). Murine models provided significant insight into the pathogenesis of PAP, when it was noted that mice deficient in granulocyte-macrophage colony-stimulating factor (GM-CSF) developed pulmonary disease with the same histologic features noted in PAP (155,156). Similar results were observed in mice deficient in the  $\beta$ c chain of the GM-CSF receptor (157,158). Evaluations of these models delineated that macrophage function was impaired leading to the accumulation of foamy macrophages in the airspaces that were filled with surfactant-rich material, an observation identical to that seen in PAP. Individuals with idiopathic PAP revealed have antibodies against GM-CSF in the serum and bronchoalveolar lavage (159,160), leading to aberrant alveolar macrophage function and accumulation of the surfactant-rich material. Subsequently, multiple studies have suggested that exogenously administered GM-CSF has a therapeutic benefit in some subjects with idiopathic PAP (161–163).

Secondary forms of PAP are caused by impaired function or decreased numbers in the macrophage population, such as can be seen with immunosuppression, some types of hematologic malignancies, some infections, and inhalation of toxic dusts or fumes (154). Congenital forms of PAP are caused by mutations in *SFTPC*, *SFTPB*, and the  $\beta$ c chain of the GM-CSF receptor (8,21,164–167). Surfactant protein B (SPB) deficiency leads to respiratory distress on the first day of life, with death typically in the first six months, with the lungs of affected infants having a histopathologic pattern similar to that seen in idiopathic PAP (164). Multiple *SFTPB* mutations have been described (165,168) and deletion of *SFTPB* in a murine model essentially recapitulated the clinical findings. *SFTPC* mutations can not only cause ILD in childhood but have also been associated with pediatric cases of PAP (21). Finally, some cases of pediatric PAP have been linked to mutations in the  $\beta$ c chain of the GM-CSF receptor (166).

#### 61.4.6 Lysinuric Protein Intolerance

Lysinuric protein intolerance (LPI) is an autosomal recessive disorder of cationic amino acid transport in the small intestine and kidney. A rare disorder, it is usually diagnosed at 5–6 years of age (169). LPI is caused by mutation in the heterotrimeric amino acid transporter (HAT)  $\gamma$ -LAT-1 gene *SLC7A* (170,171) located on chromosome 14q11.2 (172). HATs are responsible for amino acid transport, and in LPI, dibasic amino acid transport is defective, predominantly in the small intestine and

kidney epithelium, but also likely in the lung and liver (169). LIP families have been described in Italy, Finland, and Japan. Affected individuals have increased urinary excretion of arginine, ornithine, and lysine, with the low plasma concentration of these dibasic amino acids leading to urea cycle dysfunction and hyperammonemia (169). Mental retardation, delayed physical development, intestinal malabsorption, vomiting, and failure to thrive are the prominent clinical manifestations. However, respiratory disease is frequently reported as well, with progressive alveolar proteinosis or alveolar hemorrhage both described (173,174). In a study from Finland, one-third (8 of 25) of asymptomatic LPI individuals had findings suggestive of lung fibrosis on chest radiography while two-thirds (8 of 14) had ILD on computed tomography of the chest (174). While the mechanism causing surfactant accumulation is not well known, like PAP, whole-lung lavage has been associated some therapeutic benefit (175).

### 61.4.7 Neurofibromatosis

Neurofibromatosis 1 (NF1) and neurofibromatosis 2 (NF2) are autosomal dominant tumor suppressor syndromes with genetic and clinical features that are distinct from each other (176). While both forms of NF can be inherited, sporadic mutations account for approximately half the cases. NF1 has a prevalence of about 1/5000, while NF2 is much rarer, with a prevalence of ~1/200,000. Patients with NF1 typically present with cutaneous neurofibromas, Lisch nodules of the iris, café-au-lait macules, and skin freckling in intertriginous areas of the axilla or groin. Mental retardation, scoliosis, pseudoarthrosis of the tibia, hypoglycemia, hypertension, optic pathway glial tumors, pheochromocytomas, and leukemias have also been described. The skin manifestations seen in NF1 are typically absent in NF2 (176). NF1, located on chromosome 17q11.2, encodes neurofibromin, a protein involved in controlling cellular proliferation (177–179). NF2, located on chromosome 22q12.1, encodes merlin, a cytoskeletal protein (180–182). Pulmonary manifestations can occur in NF1, but are not typically seen in NF2. The degree to which pulmonary involvement occurs is not well known, with different reports describing a wide range; however, the most recent analysis reported that only 1.9% (3 of 156) individuals with NF had ILD (183). Thoracic manifestations are not limited to ILD, as individuals can also present with bronchiectasis, pulmonary hypertension, emphysema, intrapulmonary neurofibromas, intrathoracic schwannomas, AEC hyperplasia, and phrenic nerve involvement with diaphragmatic paralysis (184,185). Severe restriction on pulmonary function can occur because of scoliosis or skeletal disease affecting the chest wall. Lung biopsies from individuals with NF associated ILD reveal a peripheral and subpleural pattern similar to that observed in UIP, but

accumulation of alveolar macrophages sometimes suggests a pathologic pattern of DIP (186).

### 61.4.8 Familial Hypocalciuric Hypercalcemia

Familial hypocalciuric hypercalcemia (FHH), a disorder characterized by elevated serum calcium and magnesium and low urinary calcium secretion is caused by inactivating mutations in *CaR*, a calcium-sensing receptor gene located on chromosome 3 (187,188). *CaR* encodes a seven-transmembrane G protein-coupled receptor that functions to set the extracellular level of calcium (189). Heterozygous inactivating mutations in *CaR* decrease the sensitivity of the receptor to calcium, requiring a higher serum calcium level for reduction of parathyroid hormone release from the parathyroid glands (190) and increased reabsorption of calcium and magnesium in the nephron (191,192). When homozygous, such mutations cause lethal neonatal hyperparathyroidism (LNH) (187). In contrast, activating mutations in *CaR* also occur, resulting in autosomal dominant hypocalcemic hypercalciuria (193,194). Further, some cases of apparent idiopathic hypoparathyroidism have been explained by activating *CaR* mutations (194). A second FHH locus known as HHC3 has been mapped to 19q13 (195).

Pulmonary fibrosis was first described in association with FHH by Auwerx and colleagues (196). Patients present with pulmonary symptoms similar to those seen with the IIPs, most prominently progressive dyspnea. Recurrent lung infections are sometimes encountered, thought to be due to granulocyte dysfunction and low myeloperoxidase levels (197,198). Chest radiographic imaging may reveal reticulonodular infiltrates, while PFT reveals restriction with a reduction in diffusion capacity. Most affected individuals present in the fourth decade, and some individuals can progress to severe end-stage pulmonary fibrosis. Evaluation of bronchoalveolar lavage fluid reveals elevated cell counts including neutrophils, macrophages, and multinucleated giant cells. Lung biopsies are characterized by interstitial inflammation with conchoid-body aggregates, multinucleated giant cells, and loosely formed granulomas (196,197). The role that the *CaR* encoded calcium sensing receptor plays in the pathogenesis of ILD in this disorder remains unclear, but it is thought that it may impact the effect of some key profibrotic mediators (199).

### 61.4.9 Pulmonary Alveolar Microlithiasis

Pulmonary alveolar microlithiasis (PAM) is a rare diffuse lung disease with a likely autosomal recessive mode of inheritance, which is characterized by calcium phosphate microlith accumulation within the alveolar spaces. Over 500 individuals with PAM have been reported across the globe, with patients ranging from

infancy to 80 years of age (200). Over 100 cases have been described from Japan alone (201). Approximately 50% of the cases appear to be inherited, with consanguinity playing a prominent role (202). Using a genome wide SNP analysis, investigators evaluated Japanese PAM patients and identified homozygous mutations in the gene *SLC34A2* (201), which encodes for a type IIb sodium phosphate cotransporter. In vitro studies revealed that mutant *SLC34A2* protein led to loss of phosphate transport function. Additional studies have revealed that *SLC34A2* is highly expressed in type II AECs in the lung (203,204).

Among patients with PAM, the most common presenting symptom is dyspnea on exertion, with non-productive cough often presenting as well. On rare occasions, hemoptysis may be encountered. With PAM, innumerable alveolar calcifications develop, leading to a sandlike micronodular appearance on chest radiograph (205). A calcified reticular pattern with interlobular septal thickening in a predominantly peripheral and basal distribution is observed on computed tomography of the chest (206). Radiographic findings do not necessarily correlate well with clinical symptoms, as striking radiographic images have been noted in asymptomatic individuals. However, in the later stages of the disease, patients can present with severe pulmonary fibrosis and associated pulmonary hypertension and respiratory failure. Calcospherites may be observed on bronchoalveolar lavage, and lung biopsies reveal prominent calcified foci (200). At the present time, no effective treatments are available for PAM except for lung transplantation (207), but it is hoped that, based on the genetic link mentioned, agents targeting phosphate metabolism might one day be therapeutic.

#### 61.4.10 Lipoid Proteinosis

Lipoid proteinosis, also known hyalinosis cutis et mucosae (Urbach–Wiethe disease), is characterized by the widespread deposition of a glycoprotein material in multiple tissues including the lung (208). A rare autosomal recessive disorder, over 250 cases have been described worldwide with many cases involving consanguinity (209). In a study by Hamada and colleagues (208) in 2002, evaluation of three affected siblings from a family in Saudi Arabia linked the disease to chromosome 1q21. Further evaluation of five more families with 28 affected individuals narrowed the region of interest to 6.5 Mb, from which a candidate gene approach yielded six different homozygous mutations in the gene encoding extracellular matrix protein 1 (*ECM1*). *ECM1* is a glycoprotein implicated in angiogenesis, keratinocyte differentiation, and endobronchial bone formation (210–212).

Since multiple tissues may be affected, clinical manifestations may also be diverse, including papules in the skin and along eyelid margins, thickening of the tongue

and frenulum, skin blistering and/or scarring, alopecia, nail dystrophy, dental abnormalities, hoarseness from laryngeal involvement, epilepsy, and neuropsychiatric abnormalities (213–215). Pulmonary manifestations can occur, but are rare. Chest radiograph may reveal reticulonodular changes suggesting diffuse interstitial fibrosis (214). In affected lungs, histologic evaluation reveals expansion of amorphous eosinophilic material in the alveolar septa (216).

#### 61.4.11 Gaucher Disease

The most prevalent of the lysosomal storage diseases, Gaucher disease, is caused by defective hydrolysis of glucosylceramides (217). The disease is autosomal recessive, with most cases caused by mutations in the gene encoding for  $\beta$ -glucosidase, the enzyme responsible for catalyzing glucosylceramide (218). Some cases are caused by mutations in the genes encoding for glucocerebrosidase or lysosomal hydrolase. With the resultant decreased enzymatic activity, inclusions of glucocerebroside accumulate in macrophages in the reticuloendothelial system. Infiltration of these Gaucher cells in multiple tissues leads to neurologic impairment in the most severe (infantile-onset) forms, skeletal disease, hepatosplenomegaly, anemia, and thrombocytopenia. Lung disease may also manifest with presentations including pulmonary hypertension and/or ILD (218–220). In fact, a prospective study of Gaucher patients indicated that PFT abnormalities were quite common, with evidence of both obstruction and restriction in the cohort. Diffusion capacity abnormalities were common as well (221). Reticulonodular or miliary patterns may be noted on chest radiograph with HRCT of the chest also revealing bilateral interstitial changes, sometimes with areas of ground glass attenuation. Gaucher cells may be observed in bronchoalveolar lavage fluid (222). With lung biopsies, two histopathologic lung patterns have been described: (1) isolated alveolar space accumulation of Gaucher cells and (2) infiltration of Gaucher cells into the alveolar, interstitial, and pleural components (223). Exogenous  $\beta$ -glucosidase therapy can be employed to treat Gaucher disease, with some reports suggesting that pulmonary abnormalities slowing improving with this enzyme replacement therapy (218,224).

#### 61.4.12 Niemann-Pick Disease

Niemann-Pick disease (NPD) is a lipid storage disease in which sphingomyelin and cholesterol accumulate in the cell (225,226). A rare autosomal recessive disorder, NPD has six variants (A–F). In NPD, lipid-laden Pick cells infiltrate the reticuloendothelial system, leading to hepatosplenomegaly and anemia because of bone marrow involvement. Patients with type A NPD have variable degrees of neurologic involvement, with

some cases of severe neurodegeneration and death in childhood. In contrast, patients with type B NPD survive into adulthood without manifesting neurologic disease. Biochemical defects vary across the six subtypes and range from deficiency of lysosomal sphingomyelinase to alterations in cholesterol processing in the cell (226). As examples, NPD types A and B result from mutations in the *SMPD1* locus (located on chromosome 11p15.4-15.1), types C1 and D from *NPC1* mutations (located on 18q11-18q12), and type C2 from *NPC2* (*HE1*) mutations (located on 14q24.3). Parenchymal lung tissue infiltration and fibrosis can occur, and is typically more common in the neuronotropic infantile forms than in the adult forms. PFTs may reveal restriction and a decrement in the diffusing capacity, and patients may have oxygen desaturation (227–230). Radiologic imaging reveals predominantly basilar reticulonodular infiltrates on chest radiographs (231) and upper lung zone nodular and ground-glass changes and lower lung zone interlobular septal thickening on HRCT (228). On lung biopsy specimens, NP cells accumulate in the interstitium and alveoli, histiocytes are present, and the alveolar septa are expanded with excess matrix.

### 61.4.13 Fabry Disease

Fabry disease is a lysosomal storage disorder of glycosphingolipid metabolism due to deficiency of  $\alpha$ -galactosidase A ( $\alpha$ -gal A). The  $\alpha$ -galactosidase gene (*GLA*) is located on chromosome Xq22, with multiple mutations reported that result in loss of function of the encoded enzyme (232,233). As might be expected, disease manifestations are more severe and occur earlier in men, but women can be affected by the disease as well. With deficiency of  $\alpha$ -galactosidase A, catabolism of glycolipids is impaired, leading to their accumulation in the vascular endothelium as well as visceral tissues. The disease commonly affects the skin, with the appearance of angiokeratoma, a characteristic early sign. Involvement of the renal and cardiovascular systems is common, with renal failure, myocardial infarction, heart failure, and stroke the major causes of death. The lungs can be affected as well by glycolipid accumulation, with pulmonary manifestations including dyspnea, oxygen desaturation, airway obstruction, wheezing, hemoptysis, pneumothorax, frequent respiratory infections, pulmonary vascular infiltration, and interstitial infiltrates. Enzyme replacement therapy with human  $\alpha$ -gal A is now used to treat Fabry disease; this treatment reduces painful crises, improves quality of life (234,235), reduces cardiac hypertrophy, stabilizes renal function (235), and improves pulmonary symptoms and oxygenation (236).

### 61.4.14 GM<sub>1</sub> Gangliosidosis

GM<sub>1</sub> gangliosidosis is a rare storage disorder resulting from  $\beta$ -galactosidase deficiency. Also known as

Morquio syndrome type B or mucopolysaccharidosis type IVB, the disease is secondary to mutations in the gene for  $\beta$ -galactosidase on chromosome 13p21.33 (237). Affected individuals have severe cerebral degeneration that usually leads to death before a year of age. GM<sub>1</sub> ganglioside accumulates in neurons, reticuloendothelial cells, and renal epithelial cells, and causes hepatomegaly and skeletal deformities. Pulmonary involvement with respiratory insufficiency has been reported in some individuals. Miliary and reticulonodular changes are observed on chest radiography while foamy macrophage infiltration of the alveoli is seen on lung histology (238,239).

### 61.4.15 Marfan Syndrome

Marfan syndrome is a hereditary disorder with prominent skeletal, cardiovascular, or ocular manifestations and is caused by mutations in the gene for fibrillin-1 (*FBN-1*) on chromosome 15q21.1 (240–242). Fibrillin is a large glycoprotein that not only is involved in the structural framework of the connective tissue, facilitating elasticity, but also regulates the activity of TGF- $\beta$ . Prominent skeletal manifestations include tall stature, long limbs, anterior chest deformity, scoliosis, high arched palate, and joint laxity. Subluxation of the lens is the most clinically important ocular finding. Cardiovascular complications can be severe and include aortic aneurysm, annuloaortic ectasia, and mitral and aortic valvular regurgitation, with acute aortic dissection the leading cause of early death. The most common pulmonary presentation is spontaneous pneumothorax. While interstitial fibrosis in the apices has been described, it is rare. In contrast, restriction on the pulmonary system caused by thoracic skeletal abnormalities such as pectus deformities and scoliosis are commonly encountered (243,244).

### Biographies

**William E Lawson, MD**, is an Assistant Professor of Medicine in the Division of Allergy, Pulmonary, and Critical Care Medicine at Vanderbilt University School of Medicine in Nashville, Tennessee. A graduate of the University of Tennessee School of Medicine, Dr Lawson performed his internal medicine residency, chief medical residency, and pulmonary and critical care fellowship at Vanderbilt. Since joining the faculty as a physician-scientist at Vanderbilt in 2004, Dr Lawson has pursued research in the area of pulmonary fibrosis, with investigations including bench studies that utilize animal models of lung fibrosis as well as clinical evaluations of subjects in familial interstitial pneumonia kindreds. Dr Lawson has received external grant funding from the National Institutes of Health National Heart Blood and Lung Institute, the American Lung Association, the American Thoracic Society, and the Parker B Francis Pulmonary Fellowship Program. His clinical duties include intensive care unit and pulmonary consult service coverage at the Nashville Veterans Affairs Medical Center.

**James E Loyd, MD**, is the Rudy W Jacobson Professor of Medicine in the Division of Allergy, Pulmonary, and Critical Care Medicine at Vanderbilt University School of Medicine in Nashville, Tennessee. A graduate of West Virginia University College of Medicine, Dr Loyd performed his internal medicine residency, chief medical residency, and pulmonary and critical care fellowship at Vanderbilt. Dr Loyd's research and clinical interests span a broad category of pulmonary diseases, including mediastinal fibrosis, lung transplantation, pulmonary hypertension, and pulmonary fibrosis. Through clinical interactions with patients and families, Dr Loyd assembled large familial cohorts of both pulmonary hypertension and pulmonary fibrosis. From these family registries, Dr Loyd's research linked cases of familial pulmonary arterial hypertension to mutations in the gene encoding bone morphogenetic protein receptor 2 and cases of familial interstitial pneumonia to mutations in the genes encoding surfactant protein C, telomerase reverse transcriptase, and telomerase RNA component. Dr Loyd is central to Vanderbilt's Idiopathic Pulmonary Fibrosis (IPF) Clinical Research Program, including serving on the steering committee for the NIH IPF Network. Dr Loyd has received grant funding from the National Institutes of Health National Heart Blood and Lung Institute, including program project grants in pulmonary hypertension and pulmonary fibrosis.

### GLOSSARY

- Amnion nodosum** – a nodular condition of the fetal surface of the amnion, observed in oligohydramnios associated with absence of the kidneys of the fetus.
- Cloaca** – the structure at the far end of the hindgut that divides to form a rectum, a bladder, and genitalia.
- Gubernaculum** – the fetal ligament attached at one end to the lower end of the epididymis and testis and at the other end to the bottom of the scrotum; it is present during the descent of the testis into the scrotum and then atrophies.
- Mesonephric (Wolffian) duct** – an embryonic duct of the mesonephros, which in the male develops into the epididymis, ductus deferens and its ampulla, seminal vesicles, and ejaculatory duct and in the female is largely obliterated.
- Nephrogenic blastema (or metanephric mesenchyme)** – developmental precursor that gives rise to the nephrons in the kidney.
- Paramesonephric duct** – either of the paired embryonic ducts developing into the uterine tubes, uterus, and vagina in the female and becoming largely obliterated in the male.
- Pelvic ectasia** – dilation of the renal pelvis and calyces without any evidence of obstruction.
- Renal dysplasia** – kidney that contains poorly branched and abnormally differentiated nephrons and collecting ducts, increased stroma and occasionally, cysts and metaplastic tissues such as cartilage.
- Renal hypoplasia** – abnormally small kidney (two standard deviations smaller than the mean size for age) that contains intact nephrons that are reduced in number.
- Urachus** – a canal connecting the bladder of the fetus with the allantois, a structure that contributes to the formation of the umbilical cord. The lumen of the urachus is

normally obliterated during development, transforming the urachus into a solid cord, a functionless remnant. If still patent at birth, urine will leak from the umbilicus.

**Ureteric bud** – developmental precursor that branches in a highly reproducible manner; at each ureteric bud tip nephrons are induced. These branches will form the collecting system, including collecting ducts, renal pelvis, ureter, and bladder trigone.

**Verumontanum** – an elevation, or crest, in the wall of the urethra where the seminal ducts enter it.

### 62.1 INTRODUCTION

Congenital anomalies of the kidney and urinary tract (CAKUT) include anomalies of the kidneys, ureters, bladder, and urethra. CAKUT occurs in approximately 1 in 500 fetal ultrasound examinations (1) and represents 35–45% of all congenital abnormalities. Anomalies specific to the kidney are found in 3–6 per 1000 births. In necropsy studies of infants and children up to age 12 years, congenital anomalies of the kidney and urinary tract are present in 2–6.3% (2,3). As expected by the high incidence rate, many cases of CAKUT remain asymptomatic (3).

CAKUT occurs frequently with other structural anomalies (3) and associated syndromes. Accepted classifications of renal anomalies have avoided classifying multiple malformation disorders, placing them in one category: genetic causes (4). This chapter is divided into three main categories: (i) errors of organogenesis, (ii) errors of migration and position, and (iii) obstruction. Associated anomalies are common in disorders with errors of organogenesis. More discrete anomalies result

from disorders of histogenesis. Contiguous anomalies in the caudal part of the embryo provide evidence for developmental fields. Noncontiguous anomalies most likely result from expression of genes important for development expressed at different times during embryogenesis.

## 62.2 CLINICAL FEATURES

Structural anomalies of most organ systems have an increased risk for associated CAKUT (Table 62-1). CAKUT associated with other major anomalies, increased minor anomalies, or recurrence within a family is probably caused by an underlying syndrome or a monogenic or chromosomal disorder. In evaluating a family for inheritance of CAKUT, it is important to remember that many CAKUT cases are asymptomatic and that abdominal examination fails to detect most malformations. However, there is improved detection of clinically

significant CAKUT by routine ultrasonographic screening. A trial of early screening by renal ultrasonography in 5700 healthy 1-month-old infants in Japan was effective in detecting CAKUT in 3.5%, and surgical intervention occurred as a result of screening in 0.1% (5). In screening 6088 full-term newborns after 72 h of life with abdominal ultrasound, Hálek et al. discovered renal abnormalities in 250, some of whom required surgery (6). Because universal newborn screening for CAKUT in infants is not currently in practice, search for an underlying disease is recommended in individuals with structural anomalies that place them at increased risk for CAKUT (Table 62-1) or with the following clinical signs and symptoms:

Abnormal kidneys on prenatal ultrasound  
Anuria-oliguria  
Poor urinary stream  
Edema

**TABLE 62-1 Frequency of Urinary Tract Anomalies in Cases with Other Structural Defects**

Structural Anomaly/ Pattern	Percentage with Urinary Tract Anomalies	Most Common Urinary Tract Defects (in Relative Order of Frequency)
Absent gall bladder	32	Cystic dysplasia, renal agenesis, horseshoe kidneys
Agenesis of the corpus callosum	45–55	Reflux, ureterocele, unilateral renal agenesis, crossed fused renal ectopia, bladder diverticulae
Anencephaly	5–16	Hydronephrosis, horseshoe kidneys, polycystic kidneys, renal agenesis, renal hypoplasia, urethral atresia
Anorectal malformation	26–58 <sup>a</sup>	Hydronephrosis, unilateral renal agenesis, cystic dysplasia, reflux, cystic dysplasia, renal ectopia, cloacal exstrophy
Biliary atresia	3	Double ureter, hydronephrosis, renal cysts
Caudal dysplasia	40	Renal agenesis, hypoplasia, cystic dysplasia; horseshoe kidneys, crossed renal ectopia, urachal anomalies
CHARGE	42	Unilateral renal agenesis, hydronephrosis, renal hypoplasia
Diaphragmatic hernia	15–18	Renal agenesis, cystic dysplasia, hydronephrosis, ureteropelvic obstruction
Esophageal atresia and tracheoesophageal fistula	33	Unilateral renal agenesis, horseshoe kidneys, reflux
Gastroschisis	15	Unilateral renal agenesis, horseshoe kidneys
Heart defect	5–39 <sup>a</sup>	Duplex collecting system, unilateral renal agenesis, renal ectopia
Lateral body wall defect	50–65	Renal agenesis, urethral atresia, hydronephrosis
Limb reduction defects	9	Renal agenesis, hydronephrosis, cystic dysplasia, horseshoe kidney
MURCS association	28–80	Renal agenesis, renal ectopia
Myelomeningocele	9	Renal agenesis, horseshoe kidney
Omphalocele	11–47	Cloacal exstrophy, horseshoe kidneys, patent urachus
Oral clefts	4	Renal agenesis, horseshoe kidney
Penoscrotal transposition	90	Renal agenesis, cystic dysplasia, ectopia, horseshoe kidneys
Persistent cloaca	83	Cloacal and bladder anomalies
Pulmonary hypoplasia	18–21	Cystic dysplasia, renal agenesis, horseshoe kidney, polycystic kidney, urethral atresia
Single umbilical artery (isolated)	26	Dilated renal pelvis, duplicated renal pelvis, reflux, hydronephrosis, horseshoe kidneys, unilateral renal agenesis
Sirenomelia	100	Renal agenesis, cystic dysplasia, urethral atresia
Supernumerary nipples	4	No specific pattern
Tracheal agenesis	38	Renal agenesis, cystic dysplasia, horseshoe kidney
VACTERL association	82–87	Reflux, unilateral renal agenesis, ureteropelvic junction obstruction, crossed fused ectopia
Vertebral defects	27–46	Unilateral renal agenesis, duplicated ureter, renal ectopia, horseshoe kidney

<sup>a</sup>Higher numbers seen in autopsy series and/or those with  $\geq 3$  congenital anomalies.

 Aniridia, hemihypertrophy  
 Preauricular pits or ear tags accompanied by any of the following: dysmorphic features; facial asymmetry; coloboma; choanal atresia; jaw hypoplasia; branchial cysts or sinuses; cardiac murmurs; distal limb anomalies; imperforate or anteriorly placed anus; family history of deafness; or a maternal history of gestational diabetes (7).

## 62.3 GENETICS

Over 250 syndromes and monogenic disorders have been reported to have an increased risk for CAKUT (4,8–11). Many isolated structural anomalies of the urinary tract have multifactorial inheritance and an empiric recurrence risk that is greater than the background population risk. The type of anomaly is frequently helpful in revealing the nature of the underlying disorder and the presence of other medically significant structural anomalies. Disorders associated with specific renal anomalies are summarized in the tables of each section. CAKUT associated with chromosome abnormalities and teratogen exposures are summarized in Tables 62-2 and 62-3.

## 62.4 ERRORS OF ORGANOGENESIS

### 62.4.1 Renal Agenesis

Unilateral or bilateral renal agenesis refers to the complete absence of one or both kidneys. The presence of residual renal tissue with or without the ipsilateral ureter, by definition, excludes a diagnosis of renal agenesis. Estimates of the prevalence of unilateral renal agenesis from autopsy studies range from 1:52 to 1:1286; one study showed the incidence in newborns to be 0.15 per 1000 (12). Newer studies note an incidence of unilateral renal agenesis as 1 in 5000 newborns (13,14). The incidence of renal aplasia, defined as the presence of renal parenchyma without any function is 1 in 1300 (15). Interestingly, Hiraoka et al. (15) proposed that a significant proportion of renal agenesis diagnosed clinically thus far might more correctly be renal aplasia. In their study, ultrasounds in the neonatal period could identify the aplastic kidney, which had a reniform shape, not rudimentary, during the newborn period, and regressed rapidly thereafter.

The incidence of bilateral renal agenesis is variable, depending on the method of ascertainment and the age of the cohort. An incidence of 0.12 per 1000 newborns was reported in a population study in British Columbia (12). The sex ratio shows a male predominance of 2.45:1. In 12,000 autopsies of fetuses and infants less than 1 year old, 1 of 240 had bilateral renal agenesis (16,17), compared with 1 of 2653 and 1 of 2812 of autopsies of children under age 15 years and of all ages, respectively (18). More recent studies note an incidence of bilateral renal agenesis as 1 in 30,000 newborns (13,14).

**62.4.1.1 Clinical Features.** Bilateral renal agenesis presents in utero with severe oligohydramnios as early as 14 weeks gestation. At birth, bilateral renal agenesis presents with severe respiratory distress due to pulmonary hypoplasia secondary to inadequate renal function and inadequate amniotic fluid during pregnancy, nonpalpable kidneys, and morphologic features of Potter sequence (16). Unilateral renal agenesis may be detected on ultrasonographic screening, or secondary to investigation for symptoms of genitourinary tract disease. The majority of individuals with unilateral renal agenesis are asymptomatic and identified because of other medical problems or at autopsy.

Associated congenital anomalies appear frequently, most commonly involving (i) contiguous structures of the renal developmental field, (ii) noncontiguous structures, and (iii) deformations resulting from oligohydramnios. Anomalies of the contiguous structures in bilateral renal agenesis include complete and bilateral absence of the ureters and hypoplasia of the bladder. In 85% of females, the vagina and the uterus (paramesonephric duct derivatives) are absent or abnormal. In males, the testes are usually undescended, and the ductus deferens and the seminal vesicles (mesonephric duct derivatives) are abnormal or absent (17). With unilateral renal agenesis, the ipsilateral ureter and fallopian tube may be absent, and various uterine and vaginal abnormalities may occur. In 60% of patients, other anomalies of the contiguous developmental fields, including anal atresia, imperforate anus, malrotation, and Meckel diverticulum are present, and 33–99% have sacral and coccyx anomalies, sirenomelia, and talipes equinovarus (4).

Frequently, anomalies of noncontiguous structures are found (17), especially limb malformations, cardiac anomalies (19), tracheal agenesis (20), esophageal or duodenal atresia, cleft lip or palate, hydrocephalus (21), and other brain malformations.

Oligohydramnios results in anomalies due to deformation (Potter sequence), including breech presentation (60%), apparent hypertelorism, infraorbital creases, flattened nasal tip, hypoplastic mandible, enlarged and posteriorly rotated ears, redundancy of skin, dry skin, genu varum, talipes, and metatarsus adductus (4,8). Pulmonary hypoplasia, with arrest of alveolar development at 12–16 weeks gestational age, occurs because of either severe oligohydramnios or the underlying disorder.

**TABLE 62-2 Common Chromosomal Disorders Associated with Urinary Tract Anomalies**

Chromosome Disorder	Urinary Tract Anomaly	Frequency
2q terminal deletion	Wilms tumor, horseshoe kidney, dysplastic kidney, renal hypoplasia, ureteral stenosis	11%
4p	Renal agenesis or hypoplasia, vesicoureteral reflux, hydronephrosis	33%
4q partial duplication	Horseshoe kidney, renal hypoplasia, renal duplication, ectasia of distal tubule	Frequent
5p	Horseshoe kidney, renal agenesis, renal duplication, ectasia of distal tubules	Occasional
6q partial duplication	Unilateral renal agenesis, cystic dysplasia	Uncertain <sup>a</sup>
7 trisomy	Cystic dysplasia, enlarged kidneys	Frequent
7q partial deletion (Williams–Beuren)	Renal aplasia/hypoplasia, duplicated kidney, bladder diverticula	18%
8 trisomy, 8 trisomy mosaicism	Cystic dysplasia, enlarged kidneys, small cortical cysts, hydronephrosis, duplication of kidneys/ureters/pelvis	Frequent
9p partial duplication	Horseshoe kidney, hydronephrosis	Frequent
9 trisomy	Hydronephrosis, cystic dysplasia, duplication kidneys and ureters	Frequent
10p partial duplication	Unilateral agenesis, cystic kidney, renal dysplasia	Uncertain
10q partial duplication	Hypoplastic kidney, hydronephrosis	Frequent
11p13 deletion	Wilms tumor	Frequent
13q	Hydronephrosis, vesicoureteral junction obstruction	Uncommon
13 ring	Renal hypoplasia and ectopy, duplication of kidney and ureter, unilateral renal agenesis, polycystic kidney	Frequent
13 trisomy	Hydronephrosis, cystic dysplasia, micropolycystic dysplasia, hydroureter, horseshoe kidney, ureteral duplication, duplication of renal pelvis, small cortical cysts	60–70%
17p partial deletion (Smith–Magenis)	Variable; no characteristic structural abnormality	19%
17p13.3 deletion (Miller–Dieker)	Cystic or pelvic kidney	Uncertain
18q	Horseshoe kidney, unilateral agenesis, hydronephrosis	40%
18 ring	Hydronephrosis, tubular dilation	20%
18 trisomy	Horseshoe kidney, ectopia, ureteral duplication, cortical cysts, exstrophy of the cloaca, hydronephrosis	70%
21q	Unilateral renal agenesis, abnormal kidney shape, dilated calyces	Uncertain <sup>a</sup>
21 trisomy	Renal agenesis, hypoplasia, horseshoe kidney, posterior urethral valves, hydronephrosis, ureteropelvic junction obstruction, vesicoureteral reflux, fetal hydronephrosis	3–7%
22q11 deletion	Renal agenesis, dysplasia, multicystic kidneys	36%
22 partial trisomy	Renal agenesis, horseshoe kidney, hydronephrosis	Frequent
22 partial tetrasomy (cat eye)	Unilateral or bilateral renal agenesis, hydronephrosis, supernumerary kidneys	Occasional
45,X (plus other Turner karyotype abnormalities)	Horseshoe kidney, duplication collecting system, abnormal rotation, ureteropelvic junction obstruction, cystic malformation of collecting tubules; cystic, double, and ectopic kidneys, intrarenal vascular changes	60–80%
XXXXY	Hydronephrosis	10%
XXXXX	Renal hypoplasia, dysplasia	Uncertain <sup>a</sup>
XXY (Klinefelter)	Renal cysts, hydronephrosis	Uncertain <sup>a</sup>
Triploidy	Hydronephrosis, renal cysts, polycystic kidneys, cystic dysplasia	Frequent

<sup>a</sup>Reported abnormalities may not be in excess over background risk for all urinary tract anomalies.

Single umbilical artery was present in 12% of fetuses and stillbirths with bilateral renal agenesis in an autopsy series reported by Potter (16). Amnion nodosum usually accompanies oligohydramnios.

**62.4.1.2 Pathogenesis.** Renal agenesis results from an error in embryogenesis occurring before the end of week four of development (4). Complete absence of the kidney is hypothesized to result from failure of the ureteric bud derived from the wolffian (or mesonephric) duct to make contact with the nephrogenic blastema (or metanephric mesenchyme); this can result from the absence of the wolffian duct, failure of the ureteric bud to form, failure of the bud to reach the blastema, an inadequate inductive influence at the appropriate time in embryogenesis, or absence of the metanephrogenic mesenchyme. There are numerous transcription/growth factors and

intracellular signaling molecules that are involved in the induction networks that signal the kidney and ureteral precursors. Key to the induction of the outgrowth of the ureteric bud from the mesonephric duct appears to be the expression of the signaling molecule glial-derived neurotrophic factor (GDNF) secreted from the metanephric mesenchyme, which then binds to its receptors rearranged during transfection (RET) and GDNF-family receptor  $\alpha 1$  (GFRA1) in the mesonephric duct (22,23). A disruption of this GDNF-RET signaling pathway has been implicated in renal agenesis and hypodysplasia.

GDNF levels and its spatial expression are regulated by multiple transcription factors such as Eyes absent homolog 1 (EYA1) (24,25), the sine oculis homeobox homologs SIX1 and SIX4 (26,27), Sal-like 1 (SALL1) (28), members of the paired-box gene family (PAX2)

**TABLE 62-3 Urinary Tract Anomalies Associated with Teratogen Exposures**

Teratogen	Major Features	Renal Anomaly
Alcohol	Prenatal onset of growth retardation, microcephaly, hypotelorism, short palpebral fissures, smooth philtrum, variable other structural anomalies, including heart and skeletal anomalies	Small rotated kidneys, horseshoe kidney, renal dysplasia, micromulticystic dysplasia, hydronephrosis
Alkylating agents (busulphan, chlorambucil, cyclophosphamide, mechlorethamine)	Growth retardation; cleft palate; microphthalmia; digit anomalies; cardiac defects; anomalies of larynx, trachea, and esophagus	Agenesis of kidneys, hydronephrosis, hydroureter
Angiotensin-converting enzyme (ACE) inhibitors	Growth retardation, hypocalvaria, pulmonary hypoplasia oligohydramnios, patent ductus arteriosus, limb anomalies, fetal hypotension, increased fetal and neonatal mortality	Glomerulopathy, interstitial nephritis, nephrotic syndrome, progressive renal failure, renal artery stenosis, anuria, neonatal acute kidney injury, renal tubular dysgenesis
Cocaine	Structural anomalies resulting from vascular disruption	Renal and ureteral agenesis, hydronephrosis, prune-belly syndrome, hypospadias, ambiguous genitalia
Maternal diabetes	Caudal regression, neural tube defects, congenital heart, and other anomalies	Renal agenesis, ureter anomalies, urethral anomalies, cystic dysplasia
Rubella	Cataracts, microphthalmia, pigmentary retinopathy, growth retardation, heart anomalies (patent ductus arteriosus, peripheral pulmonary stenosis), skeletal anomalies, sensorineural deafness, neurologic impairment, microcephaly	Stenosis of renal artery, polycystic kidney, duplication of the ureters, unilateral renal agenesis
Thalidomide	Limb reduction anomalies, micrognathia, neural tube defects; vertebral, heart, and visceral anomalies	Renal agenesis, obstructive uropathy, abnormal kidney rotation, pelvic kidney, horseshoe kidney
Trimethadione	Distinctive facial features, developmental delay, prenatal and postnatal growth impairment, omphalocele; heart, skeletal, and limb anomalies	Absent kidney and ureter, fetal lobulation of kidneys
Vitamin A congeners	Micrognathia, cleft palate, microphthalmia, midfacial hypoplasia, hearing anomalies, anotia, microtia, neural tube defects	Hypoplastic kidneys, hydronephrosis

(29), members of the HOX11 paralogous family (30), and signaling molecule growth and differentiation factor 11 (GDF11) (31). Mutations in EYA1 (32), SIX1 (33) or SIX5 (34), all regulators of GDNF, result in brachio-oto-renal syndrome, which is characterized by defects in branchial arch, ear and renal development. Heterozygous mutations in SALL1 are implicated in Townes-Brocks syndrome, characterized by external ear anomalies with sensorineural hearing loss, limb anomalies, and renal and anorectal malformations (35). Recent papers have identified heterozygous mutations in *RET* and *UPK3A* genes in individuals with renal agenesis (36–38).

In addition to anomalies due to errors in embryogenesis of the mesonephric and paramesonephric ducts, abnormalities of the hindgut and cloacal membrane are common. A larger field of abnormal embryonic development can affect the entire caudal end of the embryo (e.g. caudal regression sequence and sirenomelia). Other developmental field defects that are frequently associated with renal agenesis are the acrorenal field defect (limb, renal, and other anomalies), the MURCS association (Mullerian duct aplasia, renal aplasia, cervicothoracic somitic (vertebral) defects, hypoplastic uterus, absent vagina, short stature)

(39), the VACTERL association (vertebral defects, anal atresia, cardiac defect, tracheoesophageal fistula, renal anomalies, limb anomalies), the CHARGE syndrome (coloboma, heart defect, choanal atresia, mental retardation, genital hypoplasia, ear anomalies, growth impairment, deafness), and the cerebro-renal-digital field defect (brain malformations and digital, renal, and other anomalies).

**62.4.1.3 Genetics.** There is etiologic heterogeneity for unilateral and bilateral renal agenesis (Tables 62-4–62-6). Reviews of newborns with the Potter sequence have determined that approximately 80% of cases are non-syndromic (40). Of newborns with Potter sequence due to all causes, 21% have bilateral renal agenesis; 48% cystic dysplasia; 25% obstructive uropathy; and 6% other renal pathology.

Hereditary factors are partly responsible for renal agenesis, as evidenced by familial aggregation of disease. For example, using renal ultrasound, Roodhooft et al. (40) found a 9% incidence rate of asymptomatic urogenital malformations and a 4.4% incidence rate of renal malformations in first-degree relatives of patients with congenital absence or severe dysgenesis of both kidneys. Familial recurrence with autosomal dominant and recessive patterns

**TABLE 62-4 Renal Agenesis: Disorders with Multiple Congenital Anomalies**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Acrorenal field defect syndromes	Limb anomalies, variable other anomalies (Table 62-5)	Renal agenesis, dysplasia, hypoplasia or ectopia	Heterogeneous	
Alagille (arteriohepatic dysplasia)	Peripheral pulmonary stenosis, biliary tract anomalies, bile duct atresia, posterior embryotoxon, skeletal anomalies	Renal dysplasia, renal cysts, renal artery stenosis, mesangiolipidosis, azotemia, nephrolithiasis, urinary concentrating defects, small kidneys, single kidney, microcystic tubular dilation with interstitial fibrosis	AD (118450)	<i>JAG1</i> <i>NOTCH2</i>
Branchio-oculo-facial syndrome	Branchial defects, lacrimal duct obstruction, pseudocleft of upper lip	Renal agenesis	AD (113620)	<i>TFAP2A</i>
Branchio-oto-renal	Mixed hearing loss, pinnae anomalies, branchial cleft fistulas, preauricular pits, Mondini cochlear malformations	Renal agenesis, cystic dysplastic kidneys ureteral anomalies, calyceal cyst or diverticulum	AD (113650)	<i>EYA1</i> <i>SIX1</i> <i>SIX5</i>
Campomelic dysplasia	Congenital bowing or angulation of long bones, cleft palate, sex reversal (XY female), respiratory tract and brain anomalies, other skeletal anomalies	Renal agenesis or dysplasia	AD (114290)	<i>SOX9</i>
Caudal dysplasia (caudal regression)	Sacral agenesis/hypoplasia, lower limb anomalies, anal atresia, genital anomalies	Renal agenesis or dysplasia; anomalies of ureters, urethra and bladder	Heterogeneous, maternal diabetes in some patients	
Cerebro-renal-digital syndromes	See Table 62-6	Renal agenesis, dysplasia, or ectopia; ureteral anomalies	Heterogeneous	
CHARGE syndrome	Coloboma, heart defect, choanal atresia, mental retardation, genital hypoplasia, ear anomalies, growth impairment, deafness	Renal agenesis, cystic renal dysplasia, ureteral abnormalities, fused/ectopic kidneys	AD (214800)	<i>CHD7</i>
CHILD syndrome	Congenital hemidysplasia, ichthyosiform erythroderma, and limb defects	Unilateral renal agenesis Hydronephrosis	X-linked (308050)	<i>NSDHL</i>
Chromosomal abnormalities	See Table 62-2			
Cornelia de Lange	Distinctive facies, microcephaly, short stature, micromelia, oligodactyly, mental retardation	Renal agenesis, dysplasia, or hypoplasia	AD (122470)	<i>NIPBL</i>
Diabetes, maternal	Prenatal overgrowth, caudal regression, neural tube defects, congenital heart defects	Renal agenesis, ureteral and urethral anomalies	Metabolic teratogens	
Digeorge syndrome	Sacral meningocele, hydrocephalus, conotruncal heart anomalies	Unilateral renal agenesis, dysplasia, hydronephrosis	AD (188400)	22q11.2 deletion
Dysgnathia complex (otocephaly)	Agnathia, synotia, microstomia, holoprosencephaly, cleft lip/palate	Renal agenesis, fusion or hypoplasia	Heterogeneous	
Early amnion rupture (ADAM, amniotic bands)	Digital and limb amputations, ring constrictions, facial clefts, body wall defects, brain anomalies	Renal agenesis, dysplasia, or ectopia; ureteric and urethral anomalies	Sporadic	
Fanconi pancytopenia	Anemia, pancytopenia, radial aplasia or hypoplasia, microcephaly, short stature, variable microphthalmia, ear anomalies, heart defects, chromosome breakage	Renal agenesis (39%) or dysplasia; duplication of pelvis and/or ureter; ectopic or horseshoe kidney, hydronephrosis	AR (227650)	<i>FANCA</i> (A, C-G, I, J, L-P)
Fraser (cryptophthalmos)	Cryptophthalmia, cleft lip/palate, genital anomalies, atresia of ear canal, anal atresia, syndactyly	Renal agenesis or dysplasia, ureteric anomalies	AR (219000)	<i>FRAS1</i>

**TABLE 62-4 Renal Agenesis: Disorders with Multiple Congenital Anomalies—cont'd**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Kallmann syndrome	Hypogonadotropic hypogonadism, anosmia, cryptorchidism	Unilateral renal agenesis	AD, AR, XLR (147950, 244200, 308700, 308750)	<i>FGFR1</i>
Lenz microphthalmia	Microphthalmia; coloboma; mental retardation; anomalies of the dental, cardiovascular, genital and skeletal systems	Renal agenesis or dysplasia, hydroureter	XLR (309800)	<i>BCOR</i>
LEOPARD syndrome	Short stature, sensorineural hearing loss, hypertelorism, hyposmia, cleft palate, pulmonic stenosis, hypertrophic cardiomyopathy, hypospadias, cryptorchidism, absent ovary	Unilateral renal agenesis	AD (151100)	<i>PTPN11</i> <i>RAF1</i> <i>BRAF</i>
Limb–body wall complex (lateral body wall defect)	Lateral body wall deficiency, limb reduction anomalies, neural tube defects, heart anomalies	Renal agenesis or dysplasia, ureter anomalies, bladder exstrophy, fused/ectopic kidneys	Sporadic	
Mayer–Rokitansky–Hauser syndrome	Absent uterus, cervix, and upper vagina; vertebral defects	Renal agenesis or hypoplasia, double anomalies	AD (277000)	
Microcephaly, congenital heart disease, unilateral renal agenesis, and hypossegmented lungs	Microcephaly, congenital heart disease, hyplobulated lungs, cleft palate, preauricular pits, hydranencephaly	Unilateral renal agenesis	AR (601355)	
MURCS association	Müllerian duct aplasia, renal agenesis, cervicothoracic somitic (vertebral) defects, hypoplastic uterus, absent vagina, short stature	Renal agenesis, dysplasia, or ectopia; ureteral anomalies	Unknown (601076)	
Neu-Laxova, type II (cerebroarthrodigital)	Microcephaly, severe growth retardation, exophthalmos, absent eyelids, micrognathia, lissencephaly, other brain anomalies, joint pterygium	Renal agenesis	AR (256520)	
Neural tube spectrum	Meningomyelocele, anencephaly, encephalocele, vertebral anomalies, midline anomalies	Renal agenesis, hypoplasia, dysplasia, or fusion; ureteral anomalies, hydronephrosis	Heterogeneous, multifactorial	
Papillorenal syndrome	Optic nerve coloboma (“morning glory” anomaly of the optic disc), renal anomalies	Oligomeganephronia, renal hypoplasia, multicystic dysplasia	AD (120330)	<i>PAX2</i>
Partial aniridia with unilateral renal agenesis with psychomotor retardation	Partial aniridia, glaucoma, mental retardation	Unilateral renal agenesis	AR (206750)	
Potter oligohydramnios sequence	Flattened facies, low-set ears, suborbital creases, wrinkled and redundant skin, pulmonary hypoplasia, skeletal deformations	Bilateral renal agenesis, aplasia, hypoplasia, or severe dysplasia	Heterogeneous (i.e. any disorder resulting in severely decreased urine production)	
Renal adysplasia	Anomalies of internal genital system, anus, heart, spine, hands, and feet	Renal agenesis, hypoplasia, or dysplasia; ureteral and urethral anomalies, 50–90% risk for any renal anomaly, 30–40% risk for bilateral renal agenesis	AD (191830)	<i>RET</i> <i>UPK3A</i>
Renal cysts and diabetes syndrome	Pancreas atrophy, diabetes, genital abnormalities	Unilateral kidney agenesis, hypoplasia, cortical atrophy, interstitial fibrosis, renal cysts	AD (137920)	<i>TCF2</i>
Renal–genital–ear	Anomalies of middle ear ossicles, kidneys, and vagina	Renal aplasia or hypoplasia	AR (267400)	

Continued

**TABLE 62-4 Renal Agenesis: Disorders with Multiple Congenital Anomalies—cont'd**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Roberts (SC phocomelia)	Prenatal growth retardation, limb malformations, craniofacial abnormalities, mental retardation	Renal agenesis, dysplasia, horseshoe kidney, polycystic kidney	AR (268300)	<i>ESCO2</i>
Sacral defect with anterior meningocele (sirenomelia)	Fusion of lower limbs, genital and cloacal anomalies, anal atresia, sacral and other vertebral anomalies	Renal agenesis or hypoplasia, dysplasia, ectopia, or fusion; ureteral and urethral anomalies	AD (600145)	<i>VANGL1</i>
Smith–Lemli–Opitz	Microcephaly, postaxial polydactyly, ambiguous genitalia, facial dysmorphism, 2–3 syndactyly, disorder of cholesterol metabolism	Unilateral renal agenesis, cystic dysplasia and fusion, hydronephrosis, ureteropelvic junction obstruction	AR (270400)	<i>DHCR7</i>
Teratogen exposures	See Table 62-3			
Thoracoabdominal syndrome	Diaphragmatic and ventral hernia, hypoplastic lung, cardiac anomalies, cleft lip/palate	Renal agenesis	X-linked (313850)	
Thymic–renal–anal–lung dysplasia	Unilobed or absent thymus, imperforate anus, unilobed lung	Renal agenesis/dysgenesis, ureteral agenesis/dysgenesis	AR (274265)	
Townes–Brocks	Anal atresia, anteriorly placed anus, radial ray duplication or reduction, ear anomalies, sensorineural hearing deficit, spectrum of hemifacial microsomia	Renal agenesis or hypoplasia, vesicoureteral reflux, posterior urethral valves, multicystic kidneys	AD (107480)	<i>SALL1</i>
Twin reversed arterial perfusion (TRAP sequence)	Co-twin with incomplete development of all organ systems, limbs, and body form; upper body more severely affected than lower body	Renal agenesis, hypoplasia or cystic dysplasia; ureteral and urethral anomalies	Sporadic, occurs in MZ twins, triplets	
Urorectal septum malformation	Pseudohermaphroditism, cloacal and Müllerian duct anomalies, ambiguous genitalia, imperforate anus	Renal agenesis, hypoplasia, and cystic dysplasia; ureteral and urethral anomalies	Sporadic, maternal diabetes in some patients	
Uterus bicornis bicollis with partial vaginal septum and unilateral hematocolpos with ipsilateral renal agenesis	Double uterus, two cervixes, partial vaginal septum	Unilateral renal agenesis	AD (192050)	
VACTERL association	Vertebral defects, anal atresia, cardiac malformations, tracheoesophageal fistula, radial ray aplasia or hypoplasia, genitourinary and limb anomalies	Renal agenesis, hypoplasia, or cystic dysplasia; ureteric and urethral anomalies	Sporadic (192350)	

AD, autosomal dominant; AR, autosomal recessive; XLR, X-linked recessive; MZ, monozygotic.

of inheritance has been reported, both with respect to rare multiple malformation syndromes (Table 62-4) and isolated renal aplasia (41–48). X-linked inheritance of renal agenesis has also been reported, as in Kallmann syndrome (49).

**62.4.1.4 Differential and Diagnosis.** Diagnosis of renal agenesis is made with abdominal ultrasound. If the ultrasound imaging is equivocal, computed tomography (CT) scan or magnetic resonance imaging (MRI) can be used for confirmation. However, CT and MRI contrast agents

should not be used in the presence of poor kidney function. Severe renal dysplasia and renal hypoplasia can present with a similar clinical presentation. Earlier investigation of the structural and functional abnormalities of the kidney with renal scan and intravenous pyelogram (IVP) was not reliable when the kidney was severely dysplastic or hypoplastic. Cystoscopy for identification of the ureteral orifice is also unreliable when there is unilateral renal agenesis because of the variable association with ipsilateral absence

**TABLE 62-5 Disorders of the Acrorenal Field Defect with Renal Agenesis**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Acrorenal mandibular	Split hand/foot; anomalies of vertebrae, ribs and uterus	Renal agenesis, polycystic kidneys	AR (200980)	
Acrorenal syndrome	Tetraectrodactyly, lobster-claw deformity, clinodactyly	Renal hypoplasia	AR (201310)	
AREDYLD	Acrorenal field defect, ectodermal dysplasia, and lipoatrophic diabetes; hypotrichosis, absent dentition, aplasia of the breast	Ureter dysfunction, secondary renal cystic disease, hypoplasia of the renal calyx	AR (207780)	
Cerebro–renal–digital syndromes	Digital and limb anomalies, brain malformations, mental retardation and other anomalies. See Table 62-6	Renal aplasia, ectopia, and cystic dysplasia; ureteral anomalies	Heterogeneous	
CHARGE syndrome	Coloboma, congenital heart anomalies, choanal atresia, mental retardation, genital hypoplasia, ear anomalies, deafness	Renal agenesis, cystic dysplasia, fusion, or ectopia; ureteric anomalies	AD (214800)	<i>CHD7</i>
Chromosomal abnormalities	See Table 62-2			
DK phocomelia	Phocomelia, encephalocele, absent corpus callosum, thrombocytopenia	Renal agenesis, fused-ectopic kidney, ureteric anomalies, horseshoe kidney	AR (223340)	
Duane-radial ray syndrome	Duane anomaly, coloboma, ear anomaly, radial ray aplasia or hypoplasia, thumb hypoplasia, preaxial polydactyly	Renal agenesis, hypoplasia, dystopia or ectopia, malrotation of the kidney, horseshoe kidney, vesicoureteral reflux, pelvicalyceal dilation	AD (607323)	<i>SALL4</i>
Ectrodactyly-ectodermal dysplasia-clefting (EEC)	Ectrodactyly, ectodermal dysplasia, cleft lip/palate, abnormal hearing, internal genital tract anomalies, anal atresia	Renal agenesis or cystic dysplasia, ureteral and bladder anomalies, duplicated collecting system	AD (129900)	<i>EEC1</i> <i>EEC2</i> <i>TP63</i>
Fanconi pancytopenia	Pancytopenia; anemia; radial aplasia/hypoplasia; microcephaly; short stature; variable eye, ear, and heart anomalies; increased chromosome breakage	Renal agenesis (39%) or dysplasia, duplication of pelvis and/or ureter, ectopic or horseshoe kidney, hydronephrosis	AR (227650)	<i>FANCA</i> (A, C–G, I, J, L–P)
Hirschsprung disease with polydactyly, renal agenesis and deafness	Hypertelorism, Hirschsprung disease, congenital sensorineural hearing loss, polydactyly	Unilateral renal agenesis	AR (235740)	
Lacrimoauriculodento-digital (Levy–Hollister, LADD)	Digital anomalies, bifid/triphalangeal thumb, aplasia or hypoplasia of lacrimal puncta and salivary glands, dacryocystitis, cup-shaped pinnae, conductive deafness, peg teeth, enamel dysplasia	Renal agenesis, nephrosclerosis	AD (149730)	<i>FGFR2</i> <i>FGFR3</i> <i>FGF10</i>
Partial lower limb duplication-renal agenesis	Partial duplication of lower leg, hyperelasticity of skin, ectopic anus	Unilateral renal agenesis, duplicated ureter, hydronephrosis	Sporadic	
Townes–Brocks	Anal anomaly, imperforate anus, bifid or triphalangeal thumbs, features of hemifacial microsomia	Renal agenesis, ureteral and urethral anomalies, renal cystic dysplasia	AD (107480)	
Ulnar-mammary (Schinzel–Pallister)	Ulnar ray defects, oligodactyly, aplasia or hypoplasia of mammary glands and nipples, hypoplasia of apocrine glands, genital anomalies	Unilateral renal agenesis	AD (181450)	<i>TBX3</i>

AD, autosomal dominant; AR, autosomal recessive.

**TABLE 62-6 Disorders of the Cerebro–Renal–Digital Field Defect Associated with Renal Agenesis and Dysplasia**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Acrocallosal	Agenesis of corpus callosum, macrocephaly, polymicrogyria, post- or preaxial polydactyly, cleft lip/palate, congenital heart anomalies, facial dysmorphism	Renal agenesis, cystic renal dysplasia	AR (200990)	<i>GLI3</i>
Acrocephalopolydactylous dysplasia	Swollen globular body, omphalocele, short limbs, overgrowth, anotia, craniosynostosis, polydactyly, lethal	Renal cystic dysplasia, hydronephrosis, megacystis, megaureter	AR (200995)	
Acrorenal–mandibular	Split hand/foot; anomalies of genitals, uterus, vertebrae, and ribs	Renal agenesis, ureteral anomalies, renal dysplasia, cystic kidneys	AR (200980)	
Cerebellar vermis aplasia with associated features suggesting Smith–Lemli–Opitz syndrome and Meckel syndrome	Agenesis of cerebellar vermis, occipital encephalocele, hepatic fibrosis, postaxial polydactyly, genital anomalies	Renal agenesis or cystic dysplasia	AR (213010)	
Cerebro–oculofacioskeletal (COFS, Pena–Shokier)	Microcephaly, hypotonia, microphthalmia, cataracts, blepharophimosis, facial dysmorphism, camptodactyly, skeletal anomalies	Renal agenesis, cystic dysplasia, and hypoplasia	AR (214150)	<i>ERCC6</i>
Cerebro–renal–digital, Kousseff type	Cerebral hypoplasia, lissencephaly, intrauterine growth retardation, talipes equinovarus	Renal dysplasia, unilateral renal agenesis	AR	
Duane–radial ray syndrome	Duane anomaly, coloboma, ear anomaly, radial ray aplasia or hypoplasia, thumb hypoplasia, preaxial polydactyly	Renal agenesis, hypoplasia or ectopia, malrotation of the kidney, vesicoureteral reflux, pelvicalyceal dilation horseshoe kidney	AD (607323)	<i>SALL4</i>
Fryns	Diaphragmatic defects, distal digital hypoplasia, distinct facial features, pulmonary hypoplasia, eye and brain anomalies, lethal	Renal dysplasia, cortical cysts	AR (229850)	
Meckel–Gruber	Occipital encephalocele, polydactyly, cleft lip/palate, microcephaly, microphthalmia, small or ambiguous genitalia, brain anomalies, biliary dysgenesis, pancreatic dysplasia	Renal cystic dysplasia or hypodysplasia, ureteral hypoplasia or aplasia, urethral agenesis, hypoplastic bladder	AR (249000)	<i>MKS1</i>
Neurofaciodigitorenal	Megaloencephaly, mental retardation, hypotonia, short stature, triphalangeal thumb, “bifid” nasal tip	Unilateral renal agenesis	AR (256690)	
Orofaciodigital, type IV (Baraitser–Burn)	Cleft palate, lobed tongue, tongue hamartoma, oral frenula, hypertelorism, polydactyly, syndactyly, porencephaly, cerebral atrophy and malformations, tibial dysplasia, mesomelic limb shortening	Renal agenesis, cystic dysplastic kidneys	AR (258860)	
Orofaciodigital, type VI (Varadi)	Lobed tongue, oral frenula, medial cleft lip, hypertelorism, central polydactyly, brachydactyly, cerebellar anomalies, Dandy–Walker anomaly, key-hole foramen magnum, brain hamartoma	Renal agenesis, dysplasia	AR (277170)	
Pallister–Hall	Hypothalamic hamartoblastoma, postaxial polydactyly, imperforate anus, prenatal growth retardation, multiple buccal frenula, lethal	Renal agenesis, renal dysplasia	AD (146510)	<i>GLI3</i>

**TABLE 62-6 Disorders of the Cerebro–Renal–Digital Field Defect Associated with Renal Agenesis and Dysplasia—cont'd**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Papillorenal syndrome	Optic nerve coloboma, “morning glory” optic nerve	Renal agenesis, hypoplasia, renal fibrosis, tubular atrophy, vesicoureteral reflux	AD (120330)	<i>PAX2</i>
Pfeiffer	Craniosynostosis, broad thumbs, broad great toes, partial syndactyly, occasional brain anomalies	Renal agenesis (unusual)	AD (101600)	<i>FGFR1</i> <i>FGFR2</i>
Renal dysplasia, retinal pigmentary dystrophy, cerebellar ataxia, and skeletal dysplasia, (Mainzer–Saldino syndrome)	Retinal dysplasia, cerebellar hypoplasia, ataxia, hepatic fibrosis, skeletal anomalies, cone epiphyses	Renal medullary cysts, renal agenesis	AR (266920)	
Rubinstein–Taybi	Broad thumbs and toes, distinctive facies, mental retardation, microcephaly, cryptorchidism, small phallus	Renal dysplasia, absent or extra kidneys, double renal pelvis, renal calculi, posterior urethral valves, abnormal bladder shape	AD (180849)	<i>CREBBP</i>
Short rib polydactyly, type II (Majewsky)	Median cleft lip; preaxial or postaxial polydactyly; short ribs and limbs; disproportionate shortening of tibia; anomalies of genitalia, larynx, epiglottis, and viscera; pachygyria; lethal	Renal dysplasia, polycystic kidneys, glomerular and renal tubular cysts	AR (263520)	<i>NEK1</i>
Short rib polydactyly, type I (Saldino–Noonan)	Extremely short and narrow thorax, marked micromelia, absent fibula, postaxial polydactyly, genital and heart anomalies, lethal	Renal agenesis and dysplasia, polycystic kidneys	AR (263530)	
Smith–Lemli–Opitz	Microcephaly, postaxial polydactyly, ambiguous genitalia, dysmorphism, 2–3 toe syndactyly, cerebral dysgenesis, hamartoma, anomalies of other organs, defect of cholesterol synthesis	Unilateral renal agenesis, horseshoe kidney, cystic dysplasia	AR (270400)	<i>DHCR7</i>
Zellweger	Hypotonia, seizures, cirrhosis, peroxisomal enzyme deficiency of dihydroxyacetone acyltransferase	Renal cortical microcysts, absent renal peroxisomes, hydronephrosis	AR (214100)	<i>PEX 1-3,5,6,10, 12-14,16, 19,26</i>

AD, autosomal dominant; AR, autosomal recessive.

of the ureter, ureteral orifice, and hemitrigone (50). However, more recently, isotopic  $^{99m}\text{Tc}$ -EC/dimercaptosuccinic acid (DMSA) scans are being used in children with renal agenesis or multicystic dysplastic kidney to detect other associated urinary abnormalities (51).

Other renal disorders that frequently appear with anuria and oligohydramnios include autosomal recessive polycystic kidney disease (ARPKD), infantile presentation of autosomal dominant polycystic kidney disease, renal tubular dysgenesis due to autosomal recessive inheritance, in utero exposure to angiotensin-converting enzyme (ACE) inhibitors, severe obstructive uropathy, chronic placental hypoperfusion, and severe perinatal asphyxia.

**62.4.1.5 Prenatal Diagnosis.** Fetal ultrasonographic examination can detect oligohydramnios as early as 14–16 weeks gestation (4). Absence of the kidneys can

be detected by ultrasound imaging as early as 15 weeks gestation; however, a confident diagnosis may not be made until after 18–19 weeks of pregnancy. Ultrasound imaging can also be used to detect unilateral renal agenesis with or without renal dysplasia. Identification of associated anomalies, including a two-vessel umbilical cord, can also be used for detection of disorders with multiple congenital anomalies. Severe oligohydramnios is a strong predictor of pulmonary hypoplasia and postnatal respiratory insufficiency.

**62.4.1.6 Management and Outcome.** Bilateral renal agenesis is associated with a grim prognosis (52). Prenatal loss is estimated to be as high as 38%. Neonatal death occurs within 24 h in a majority of affected infants, secondary to pulmonary insufficiency rather than uremia. If the pulmonary hypoplasia is not critical, chronic

peritoneal dialysis might be feasible depending on the size of the infant and presence of other comorbidities. Unilateral renal agenesis is associated with abnormalities of the remaining kidney in as high as 30–50% of individuals receiving medical attention (4). Clinical problems in the contralateral kidney include renal dysplasia and ectopy, pyelonephritis, ureteropelvic junction obstruction, ureterovesical junction obstruction, vesicoureteral reflux, and stone formation (18,51).

Doray and colleagues (53) reported a family with affected individuals in three generations. Individuals affected with, or who are obligate heterozygotes for, hereditary renal dysplasia have an empiric recurrence risk of 15–20% for having a child with unilateral or bilateral renal agenesis. Renal ultrasonographic examination of first-degree relatives and, when indicated, second-degree relatives is necessary to exclude variable expression of an autosomal dominant disorder with reduced penetrance.

In the late 1980s and early 1990s, Brenner and Chertow (54) hypothesized that low birth weight (LBW) constitutes a risk factor for diseases in adult life such as systemic arterial hypertension and chronic kidney disease (CKD); it built on the Barker hypothesis, which first established a framework for the intrauterine origin of diseases suffered in adulthood (55). They introduced concepts of nephron endowment, hyperfiltration and intraglomerular hypertension in the available nephrons for playing a potential role in the development of systemic hypertension in adulthood. A small study by Keller et al. (56) has also shown a strong correlation between the number of nephrons and the risk of developing primary hypertension, with the average white hypertensive patient having 46% fewer glomeruli than healthy individuals.

At 10-year follow-up of children with congenital solitary kidney without uropathy, there was no increased risk for systemic hypertension or proteinuria, and there was better compensation of renal function when compared to acquired solitary kidney (57,58). However, by age 30, a diagnosis of solitary kidney predicted worse outcome (hazard ratio, 2.43; 95% confidence interval (CI), 1.9, 3.7) for initiation of dialysis as compared to patients with unilateral or bilateral renal hypodysplasia (RHD), or multicystic or horseshoe kidney, independent of other prognostic factors (59).

Management is uncertain, but general recommendation is to avoid nephrotoxic medications such as nonsteroidal anti-inflammatory drugs (NSAIDs) and tubular toxins, to avoid high protein diets and to maintain a normal body weight. Ericksson et al. (60) demonstrated in a Helsinki cohort that hypertensive adults had LBW as children, and gained weight more rapidly in childhood. Hodgin et al. (61) reported cases of secondary focal segmental glomerulosclerosis (FSGS) in adults who were LBW, presumably who had lower nephron endowment. Obesity can also predispose to secondary FSGS; therefore, it is wise to maintain a normal body weight especially with unilateral renal agenesis. It is also recommended that individuals with unilateral renal agenesis

should not participate in contact sports or other activities that place the single kidney at risk of injury.

## 62.4.2 Renal Hypoplasia/Dysplasia

RHD, encompassing the diagnosis of renal aplasia, hypoplasia, and dysplasia, is the second leading cause of chronic renal insufficiency (creatinine clearance  $\leq 75$  mL/min/1.73 m<sup>2</sup>) in the pediatric population (62). In the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) database, RHD was the primary diagnosis in 17.3% of the children with CKD, 14% of children on dialysis, and 15.9% of children with renal transplants (63).

Unilateral dysplastic kidneys occur in 1 in 1000, and bilateral dysplasia in 1 in 5000 of the general population (64). Strictly speaking, renal hypoplasia is defined as a small kidney, which contains intact nephrons that are reduced in number, whereas a dysplastic kidney contains disorganized elements and poorly differentiated tissue.

**62.4.2.1 Clinical Features.** Severe renal dysplasia and renal hypoplasia can have a similar clinical presentation. These two entities can be distinguished based on histological examination of renal tissue obtained from a kidney biopsy or surgical nephrectomy, which is rarely performed for diagnostic purposes. In practice, the diagnosis of primary renal hypoplasia is favored when the following criteria are met: (i) reduction of renal size by two standard deviations from the mean size for the age, (ii) exclusion of renal scarring by DMSA scan, and (iii) presence of compensatory hypertrophy of the contralateral kidney.

**62.4.2.2 Pathogenesis.** The cause of RHD is aberrant interactions between the ureteric bud and metanephric mesenchyme. Histologically, there is a reduced number of ureteral bud branches, due to high levels of apoptosis, and nephrons that are fully formed, resulting in a small kidney size (65,66). Kidney size is largely determined by the number of nephrons that are formed during development, which ends at 32–36 weeks gestation. The average number of nephrons varies between 300,000 and 1 million in each kidney (67).

While most cases of RHD are sporadic, nonsyndromic disease, studies have discovered mutations in PAX2 and HNF1B in up to 15% of European Caucasian (68–71) and 10% of Japanese children with RHD (72). Thomas et al. (73) studied a multiethnic cohort of 73 North American children with CKD due to RHD, and found mutations only in Caucasian children (14%), perhaps because of the small sample size of the African-American children and children of more than one race.

PAX2, a member of the “paired-box” transcription factor gene family, is one of the earliest genes expressed during fetal kidney development. There is an embryonic continuum of expression of many genes, especially PAX2, in which the metanephros can develop into a normal kidney and ureter, a hypoplastic kidney with malformed ureter (underexpression of PAX2), or a tumor or multicystic dysplastic kidney (overexpression of PAX2) (74–76). Mutations in PAX2 result in renal coloboma

syndrome, characterized by optic nerve colobomas, renal hypoplasia and vesicoureteral reflux (77). Alterations in *PAX2*, which normally activates the expression of *RET* and *GDNF*, may contribute to renal hypoplasia by reducing *GDNF*-*RET* signaling (29,78). A 2007 study has also shown that a common variant of the *PAX2* gene is associated with reduced newborn kidney size (79).

Hepatocyte nuclear factor 1-beta (*HNF1B*) is a critical regulator of a genetic cascade essential to controlling the proliferation and differentiation of renal tubular epithelial cells. It also controls the expression of the *PKHD1* gene (the gene mutated in recessive polycystic kidney disease), accounting for the cystic renal phenotype in mutation carriers (80,81). The 1.4Mb region of the human chromosome 17 containing *HNF1B* is highly susceptible to copy number variation as it is flanked by areas of segmental duplications, which are sites for recurrent rearrangements (82,83). Whole gene deletions of *HNF1B* are a common finding in RHD (68,84). Less commonly other renal developmental genes, such as *EYA1*, *SIX1*, *SALL1* are implicated in RHD (70).

**62.4.2.3 Genetics.** One of the more common autosomal dominant disorders, hereditary urogenital adysplasia (OMIM 191830), can present with unilateral or bilateral renal aplasia or dysplasia or both. Although the etiology of hereditary urogenital adysplasia is heterogeneous, a *PAX2* gene mutation was found in one family with isolated renal hypoplasia (85). There are several autosomal dominant syndromes associated with RHD: renal coloboma syndrome (*PAX2*), renal cysts and diabetes syndrome (*HNF1B*), branchio-oto-renal syndrome (*EYA1*, *SIX1*), and Townes-Brocks syndrome (*SALL1*).

There is increasing research being conducted investigating the role of epigenetics in gene expression and disease causality. Epigenetic mechanisms of gene regulation include DNA or chromatin protein methylation, acetylation and chromatin remodeling. Post-translational modification of histones (via acetylation or methylation) may modify chromatin to alter gene expression. To date Patel et al. (86) demonstrated a link between *PAX2* and chromatin methylation. Future studies will hopefully elucidate further roles for epigenetic modifications in the pathogenesis of CAKUT.

**62.4.2.4 Prenatal Diagnosis.** Ultrasound imaging can also be used to detect bilateral or unilateral hypoplasia. Identification of associated anomalies, including a two-vessel umbilical cord, can also be used for detection of disorders with multiple congenital anomalies. Severe oligohydramnios is a strong predictor of pulmonary hypoplasia and postnatal respiratory insufficiency.

**62.4.2.5 Management and Outcome.** There is a strong rationale for mutation screening of all children with RHD (68–73). Clinical genetic testing is available for *PAX2* or *HNF1B*. Mutation identification may aid in monitoring for extrarenal manifestations such as diabetes with *HNF1B* mutations and eye or ear abnormalities with *PAX2* mutations. Previous reports have indicated that as many as half the mutations in *HNF1B* and *PAX2*

occur de novo (70,71,84). Knowing whether the mutation was inherited or occurred de novo would implicate a role for screening siblings of the affected individual and estimating recurrence risk.

The likelihood of chronic renal failure developing in patients with bilateral dysplasia has been correlated with a calculated glomerular filtration rate (GFR) of <15 mL/min/1.73 m<sup>2</sup> at 6 months of age; children with calculated GFR >15 mL/min/1.73 m<sup>2</sup> at that age tend to show improvement in renal function at follow-up (87). A small study by Keller et al. (56) showed a strong correlation between the number of nephrons and the risk of developing primary hypertension, with the average white hypertensive patient having 46% fewer glomeruli than healthy individuals.

### 62.4.3 Renal Cystic Disorders

Renal cystic disorders are discussed in Chapter 63 with particular reference to autosomal dominant and recessive polycystic kidney diseases, the clinical spectrum, and molecular genetics of these disorders. This chapter emphasizes monogenic, multiple congenital anomaly (MCA) (43) and chromosomal and teratogenic disorders associated with cystic diseases of the kidneys. Over 250 congenital disorders are associated with renal cystic disease, the most common of which are summarized in the tables. A population-based study in Manitoba reports a birth incidence of renal cysts of 1 in 1824 total births (19); multicystic dysplasias occur in 1 in 3226 births; cysts due to lower urinary tract obstruction occur in 1 in 13,982 births; and infantile polycystic kidney disease occurs in 1 in 20,793 births (4).

### 62.4.4 Cystic Dysplastic Kidneys

Renal dysplasia refers specifically to renal anomalies resulting from poorly branched and abnormally differentiated nephrons and collecting ducts, increased stroma and, occasionally, cysts and metaplastic tissues, such as cartilage (88). Dysplastic changes can be diffuse, segmental, or focal. Cysts may or may not be present and may vary in size. Dysplastic kidneys can present on gross examination as (i) normal or enlarged in size with multiple cysts (Potter type IIA kidney, multicystic dysplasia, multicystic kidney, and multicystic dysplastic kidney), (ii) small or rudimentary in size with few or only small cysts (Potter type IIB kidney, dysgenetic kidney, aplastic kidney, solid cystic dysplasia, or a rudimentary kidney), (iii) rudimentary nubbins of disorganized tissue with dysplastic metanephric elements resulting from severe dysplasia (renal aplasia); or (iv) segmental dysplasia with only a part of the kidney—most commonly the upper pole—involved.

The incidence of multicystic dysplasia of the kidney is estimated to be 1 in 3226 births (19). The prevalence of Potter syndrome due to renal agenesis or dysplasia in one or both kidneys is estimated at 1 in 6369 (40). Over 80 syndromes and individual case reports of MCA disorders have been reported with renal dysplasia. The most common of these disorders are given in Tables 62-6–62-8.

**TABLE 62-7 Disorders Associated with Renal Dysplasia**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Asplenia with cardiovascular anomalies	Bilateral right or left embryonic primordia, asplenia, polysplenia, complex heart anomalies	Renal dysplasia	AR (208530)	
Bardet–Biedl	Mental retardation, pigmentary retinopathy, polydactyly, obesity, hypogenitalism	Renal dysplasia, cystic tubular disease, focal segmental glomerulosclerosis, bladder detrusor instability	AR (209900)	<i>BBS 1-15</i>
Beckwith–Wiedemann	Omphalocele, macroglossia, organomegaly, islet cell hyperplasia, adrenal cytomegaly, embryonic tumors, macrosomia	Nephromegaly, renal medullary dysplasia, Wilms tumor, nephrocalcinosis	AD (130650)	<i>CDKN1C</i> imprinting error, parental disomy, duplication, inversion or translocation of 11p15.5
Branchio–oto–renal	Mixed hearing loss, Mondini cochlear malformations, pinnae anomalies, branchial cleft fistulas, preauricular pits	Renal dysplasia, agenesis, and ectopy; ureteral anomalies	AD (113650)	<i>EYA1</i> <i>SIX1</i> <i>SIX5</i>
Caudal dysplasia	Sacral agenesis/hypoplasia, lower limb and skeletal anomalies, anal atresia, anomalies of the uterus	Renal dysplasia and agenesis; anomalies of urethra, and bladder	Heterogeneous, maternal diabetes in some patients	
Cerebro–renal–digital	Digital and limb anomalies, brain malformations, other anomalies. See <a href="#">Table 62-6</a>	Renal dysplasia, ectopy, agenesis, ureteral anomalies	Heterogeneous	
CHARGE syndrome	Coloboma, heart anomalies, choanal atresia, mental retardation, genital hypoplasia, ear anomalies, deafness	Cystic renal dysplasia, renal agenesis, ureteric anomalies, fused/ectopic kidneys	AD (214800)	<i>CHD7</i>
Chromosome abnormalities	See <a href="#">Table 62-2</a>			
Cloacal exstrophy	Persistent cloaca, exstrophy of cloaca, failure of fusion of genital tubercles, omphalocele, vertebral anomalies, spina bifida cystica, abnormal genital structures	Duplication of urethra; urethral and ureteral anomalies; exstrophy of the bladder; renal dysplasia, agenesis, and ectopy	Heterogeneous	
Cornelia de Lange	Microcephaly, in utero growth retardation, distinct facies, micromelia, oligodactyly, heart and other anomalies, mental retardation	Renal dysplasia, agenesis, hypoplasia	AD (122470)	<i>NIPBL</i>
Craniosynostosis–mental retardation–clefting syndrome	Craniosynostosis (coronal), hypertelorism, choroidal coloboma, mild mesomelic shortening of limbs, developmental delay, seizures	Segmental renal dysplasia, cystic dysplasia	AR (218650)	
Cystic hamartoma of lung and kidney	Hamartomatous pulmonary cysts	Medullary dysplasia, cellular mesoblastic nephroma	Unknown	
Denys–Drash syndrome	Male pseudohermaphroditism, ambiguous genitalia, gonadal dysgenesis, gonadoblastoma	Diffuse mesangial sclerosis glomerulopathy, nephroblastoma (Wilms tumor), nephrotic syndrome, focal segmental glomerulosclerosis	AD (194080)	<i>WT1</i>

**TABLE 62-7 Disorders Associated with Renal Dysplasia—cont'd**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Digeorge syndrome	Sacral meningocele, hydrocephalus, conotruncal heart anomalies, hypoplasia of the thymus and parathyroid glands, hypocalcemia	Unilateral renal agenesis, dysplasia, hydronephrosis	AD (188400)	22q11.2 deletion
Early amnion rupture	Digital and limb amputations, ring constrictions, facial clefts, body wall defects, brain anomalies	Renal dysplasia, agenesis, and ectopy; ureteric anomalies	Sporadic	
Ectrodactyly–ectodermal dysplasia–clefting (EEC)	Ectrodactyly, ectodermal dysplasia, cleft lip/palate, abnormal hearing, internal genital tract anomalies, anal atresia	Renal agenesis or cystic dysplasia, ureteral and bladder anomalies, duplicated collecting system	AD (129900)	<i>EEC1</i> <i>EEC2</i> <i>TP63</i>
Fanconi pancytopenia	Pancytopenia; anemia; radial aplasia/hypoplasia; microcephaly; short stature; variable eye, ear, and heart anomalies; increased chromosome breakage	Renal agenesis (39%) or dysplasia, duplication of pelvis and/or ureter, ectopic or horseshoe kidney, hydronephrosis	AR (227650)	<i>FANC</i> (A,C–G,I,J,L–P)
Fraser syndrome	Cryptophthalmia, cleft lip/palate, genital anomalies, atresia of ear canal, anal atresia, syndactyly	Renal dysplasia or agenesis; ureteric anomalies	AR (219000)	<i>FRAS1</i> <i>FREM2</i>
Genitopalatocardiac	Male pseudohermaphroditism, micrognathia, cleft palate, conotruncal cardiac anomalies, other anomalies	Renal cystic dysplasia	AR (231060)	
Harrod syndrome	Arachnodactyly, hypospadias, cryptorchidism, distinctive facial features, anomalous vasculature, gut malrotation	Cortical microcysts of the kidney, renal dysplasia, ureteral anomalies, vesicoureteral reflux	?AR (601095)	
Hemifacial microsomia (oculoauriculovertebral spectrum, Goldenhar)	Facial asymmetry, epibulbar dermoid, coloboma, anotia, preauricular tags, deafness, vertebral anomalies, heart anomalies, variable brain malformations	Renal cystic dysplasia, agenesis, or ectopia; hydronephrosis and hydroureter; abnormal blood supply to kidney	Heterogeneous AD (164210)	
Hypoparathyroidism, sensorineural deafness, and renal disease	Hypoparathyroidism, sensorineural hearing loss, and renal dysplasia	Renal dysplasia, nephrosis	AD (146255)	<i>GATA3</i>
Lenz microphthalmia	Microphthalmia, coloboma; mental retardation; skeletal, dental, genital, and cardiovascular anomalies	Renal agenesis or dysplasia, hydroureters	XLR (309800)	<i>BCOR</i>
Limb-body wall complex	Lateral body wall deficiency, limb reduction anomalies, neural tube defects, scoliosis, heart anomalies	Renal agenesis or dysplasia; ureteral and urethral anomalies; fused/ectopic kidneys; bladder exstrophy	Sporadic	
McKusick–Kaufman	Hydrometrocolpos, transverse vaginal membrane, vaginal septum, postaxial polydactyly, cardiac anomalies, hypospadias	Polycystic kidney, vesicovaginal fistula, hydronephrosis (secondary to ureteral compression from hydrometrocolpos)	AR (236700)	<i>BBS6</i>
Microcephaly, hiatus hernia and nephrotic syndrome (Galloway–Mowat)	Microcephaly, seizures, psychomotor retardation, eye anomalies	Nephrotic syndrome, microcystic dysplasia, focal glomerulosclerosis, diffuse mesangial sclerosis	AR (251300)

**TABLE 62-7 Disorders Associated with Renal Dysplasia—cont'd**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
MURCS association	Müllerian duct aplasia, renal agenesis, absent vagina, uterus, cervicothoracic somitic vertebral anomalies, short stature	Renal agenesis, dysplasia, or ectopia; ureteral and urethral anomalies	Sporadic (601076)	
Multinodular goiter, cystic renal disease, and digital anomalies	Multinodular goiter, triphalangeal thumbs, preaxial polydactyly of feet	Renal dysplasia, polycystic kidney anomalies	AD (138790)	
Neural tube defects	Meningomyelocele, anencephaly, encephalocele, vertebral anomalies, anomalies of schisis association, midline anomalies	Renal agenesis, hypoplasia, dysplasia, or fusion; ureteral anomalies	Heterogeneous multifactorial	
Renal hamartomas, nephroblastomatosis, and fetal gigantism (Perlman)	Fetal macrosomia, hypotonia, psychomotor retardation, seration of upper alveolar ridge, can be perinatal lethal	Bilateral renal hamartomas, nephroblastomatosis, Wilms tumor	AR (267000)	
Nephronophthisis 2	Hypertension, pulmonary hypoplasia	Cortical microcysts, tubular atrophy, chronic tubulointerstitial nephritis, enlarged hyperechoic kidneys, absence of corticomedullary differentiation, renal failure by age 3	AR (602088)	<i>INVS</i>
Potter oligohydramnios sequence	Clinical features resulting from oligohydramnios	Bilateral renal agenesis, aplasia, hypoplasia, or dysplasia	Heterogeneous	
Renal adysplasia	Internal genital tract anomalies; occasional anomalies of anus, heart, spine, hands, and feet	Renal agenesis, hypoplasia, or dysplasia; ureteral and urethral anomalies	AD (191830)	<i>RET, UPK3A</i>
Renal–hepatic–pancreatic	See <a href="#">Table 62-9</a>			
Sacral defect with anterior meningocele (sirenomelia)	Fusion of lower limbs, sacral agenesis, anal atresia, uterine/vaginal anomalies, cardiac defects	Urethral atresia, ectopic urethra, posterior urethral valves, renal agenesis and dysplasia, ureteral and bladder anomalies	AD (600145)	<i>VANGL1</i>
Senior–Loken (renal-retinal)	Pigmentary retinal dysplasia, occasional hypotonia, seizures, hearing loss, psychomotor retardation	Renal dysplasia, juvenile nephronophthisis, medullary cystic disease	AR (266900)	<i>NPHP1</i>
Simpson–Golabi–Behmel	Prenatal and postnatal overgrowth, variable mental function, characteristic facial appearance, postaxial polydactyly, structural anomalies of organ systems	Large cystic dysplastic kidneys, hydronephrosis, duplication of renal pelvis, Wilms tumor	XLR (312870)	
Smith–Lemli–Opitz	Microcephaly, postaxial polydactyly, ambiguous genitalia, facial dysmorphism; 2–3 toe syndactyly, disorder of cholesterol metabolism	Unilateral renal agenesis or cystic dysplasia, fused kidneys	AR (27400)	<i>DHCR7</i>
Teratogen exposures	See <a href="#">Table 62-3</a>			
Tuberous sclerosis	Hypopigmented macules, adenoma sebaceum, retinal and brain tumors or phakomas, mental retardation, seizures	Renal angiomyolipomas (70%), renal epithelial cysts (20–30%), oncocytoma, renal cell carcinoma, polycystic kidney disease	AD (191100)	<i>TSC1 TSC2</i>

**TABLE 62-7 Disorders Associated with Renal Dysplasia—cont'd**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Urethral obstruction	Deficient abdominal muscle, urinary obstruction/distension, undescended testes, malrotation of the gut, clubfeet, limb reduction anomalies	Posterior urethral valves, urethral atresia, ureteral duplication, bladder distension, renal dysplasia, hydronephrosis	Heterogeneous (prune-belly syndrome)	
Urorectal septum malformation	Müllerian duct anomalies, persistent cloaca, ambiguous genitalia, imperforate anus, other anomalies	Renal agenesis, hypoplasia, and dysplasia; ureteral and urethral anomalies	Sporadic, maternal diabetes in some patients	
VACTERL association	Vertebral defects, anal atresia, cardiac malformation, tracheoesophageal fistula, radial ray hypoplasia/aplasia, genitourinary and limb anomalies	Renal agenesis, hypoplasia, and dysplasia; ureteric and urethral anomalies	Sporadic (192350)	
Zellweger	Hypotonia, seizures, cirrhosis, peroxisomal enzyme deficiency of dihydroxyacetone phosphate (DHAP) acyltransferase	Renal cortical microcysts, absent renal peroxisomes, hydronephrosis	AR (214100)	<i>PEX 1-3,5,6,10,12-14,16,19,26</i>

AD, autosomal dominant; AR, autosomal recessive; XLR, X-linked recessive.

Often associated with renal dysplasia is renal hypoplasia (earlier section), where there is a reduction in kidney size without abnormal development.

**62.4.4.1 Clinical Features.** Renal dysplasia is the most common cause of an abdominal mass in the newborn and the most common abnormality of the kidneys in children with CAKUT. The clinical signs, symptoms, and age of presentation of patients are usually determined by the severity of renal dysplasia and the associated congenital anomalies. Severe renal dysplasia can present in utero with oligohydramnios, followed by neonatal death from pulmonary insufficiency (Potter sequence). Less severe renal dysplasia includes single cysts and segmental and unilateral anomalies that may be asymptomatic and not identified on routine ultrasound imaging.

Clinical symptoms in infants and children include anuria, oliguria, impairment of urinary concentration and acidification secondary to malformed nephrons and tubules (polyuria with polydipsia, urinary salt-wasting, renal tubular acidosis), hematuria, hypertension, uremia, back pain, growth delay, chronic or progressive renal failure, renal osteodystrophy, and other symptoms of renal dysfunction. Unilateral or segmental involvement may be clinically silent, or associated with high blood pressure, and other clinical symptoms, including back pain. Single or multilocular cysts may increase the risk for renal tumors (89), but the risk for development of Wilms tumor in multicystic, dysplastic kidneys has been overemphasized (90).

Associated anomalies of other urinary tract structures, especially ureters, are present in a large majority of patients with renal dysplasia. Frequently there are anomalies of noncontiguous structures in patients with renal

dysplasia (19). Many of these anomalies are indicators of an underlying syndrome, a chromosomal, embryonic developmental field defect, or monogenic disorders.

Anomalies of noncontiguous structures often associated with bilateral renal dysplasia include cardiovascular anomalies (19), central nervous system (CNS) abnormalities (anencephaly, hydrocephalus, iniencephaly, spina bifida, and encephalocele), diaphragmatic hernia, cleft palate, microphthalmia, duodenal stenosis, imperforate anus, tracheoesophageal fistula, and bilateral absence of the radius and thumb. Cystic changes of the liver, pancreas, or other parenchymatous organs are not usually a feature of renal dysplasia, but are present in some disorders (Table 62-9).

Structural anomalies of other organ systems are frequently associated with unilateral renal dysplasia. Cardiovascular anomalies occur in 28–48% of patients (19); the contralateral urinary tract is frequently involved in the following anomalies: segmental renal dysplasia, renal hypoplasia, renal agenesis, hydronephrosis, ureterocele, ectopic ureters, duplication of the collecting system, and vesicoureteral reflux.

The most useful diagnostic investigations of the urinary tract are as follows:

1. Determination of renal function based on serum creatinine, urea, electrolytes, and creatinine clearance
2. Assessment of impaired urinary concentration and abnormal acidification in renal dysplasia
3. Renal ultrasonography for suspected structural renal anomalies and serial monitoring
4. Nuclear renography for evaluating size, morphology, and overall and segmental function of each kidney

**TABLE 62-8 Disorders with Renal Dysplasia and Anomalies in the Osteorenal Developmental Field**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Acrocephalopolydactylous dysplasia	Swollen globular body, omphalocele, short limbs, overgrowth, craniosynostosis, lethal	Renal cystic dysplasia, hydronephrosis, megabladder, megaureter	AR (200995)	
Alagille (arteriohepatic dysplasia)	Peripheral pulmonary stenosis, biliary tract anomalies, bile duct atresia, posterior embryotoxon, skeletal anomalies	Renal dysplasia, renal cysts, renal artery stenosis, mesangiolipidosis, azotemia, nephrolithiasis, urinary concentrating defects, small kidneys, single kidney, microcystic tubular dilation with interstitial fibrosis	AD (118450)	<i>JAG1</i> <i>NOTCH2</i>
Brachymesomelia-renal	Severe upper limb brachymesomelia, corneal opacities, heart anomalies, abnormalities of cranium and face	Glomerulocystic renal dysplasia, large kidneys	Isolated case (113470)	
Campomelia, Cumming type	Severe shortening and bowing of long bones, vertebral anomalies, cystic dysplasia of liver and pancreas, short gut, pulmonary hypoplasia, polysplenia	Renal cystic dysplasia	AR (211890)	
Campomelic dysplasia	Congenital bowing or angulation of long bones, other skeletal anomalies, cleft palate, sex reversal (XY female), respiratory tract and brain anomalies	Renal dysplasia, hypoplasia, and agenesis; hydronephrosis; calyceal dilation (33%)	AD (114290)	<i>SOX9</i>
Cerebrocostomandibular	Multiple posterior rib-gap defects, severe micrognathia, psychomotor retardation, anterior meningocele	Renal dysplasia, hydroureter	AD (117650)	<i>COG1</i> (2 cases)
Digitorenocerebral syndrome	Absent distal phalanges, dilated cerebral ventricle, seizures	Cystic renal dysplasia, double ureter	AR (222760)	
Ellis–Van Creveld (chondroectodermal dysplasia)	Short stature, short limbs, polydactyly, pelvic dysplasia, neonatal teeth, nail dysplasia, heart anomalies	Renal agenesis, renal dysplasia, multicystic kidneys, hypertension, nephronophthisis	AR (225500)	<i>EVC1</i> <i>EVC2</i>
Fryns	Short-limbed dysplasia, spondylocostal dysostosis, cleft palate, heart anomalies, duplication of uterus and vagina, Dandy–Walker cysts, hydrocephalus, absent corpus callosum, lethal	Renal dysplasia (hypodysplastic), hydroureter, cortical cysts	AR (229850)	
Hereditary osteolysis of carpal bones with nephropathy	Osteolysis of carpal and tarsal bones, hypotelorism, micrognathia, tall stature, proteinuria, end-stage renal disease	Arterial and arteriolar sclerosis, hematuria, azotemia, mesangial proliferation, glomerular basement membrane abnormalities, focal segmental glomerulosclerosis, nephrotic syndrome, end-stage renal disease	AD (166300)	
Hutterite cerebro-osteo-nephrodysplasia	Short stature with mild spondylorhizomelic dysplasia, failure to grow, severe mental retardation, postnatal microcephaly, seizures	Terminal nephrotic syndrome, nephrosis, proteinuria, end-stage renal disease	AR (236450)	
Jeune (asphyxiating thoracic dysplasia)	Small, bell-shaped thorax; pulmonary hypoplasia, polydactyly, variable rhizomelic limb-shortening, trident pelvis, hepatic fibrosis, pancreatic dysplasia	Renal dysplasia, glomerulonephritis, juvenile nephronophthisis, stenosis of ureterovesical junction, hydroureter	AR (208500)	

**TABLE 62-8 Disorders with Renal Dysplasia and Anomalies in the Osteorenal Developmental Field—cont'd**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Lethal short-limbed dysplasia, type Piepkorn	Lack of ossification of all bones except clavicle, extremely short limbs, cleft palate, vascular and urogenital anomalies	Renal dysplasia	Unknown	
Nail–patella syndrome	Short stature, sensorineural hearing loss, ocular anomalies, cleft lip/palate, hypoplastic or absent patella, other bony abnormalities, muscle aplasia, spina bifida	Collagenation of glomerular basement membrane, glomerulonephritis	AD (161200)	<i>LMX1B</i>
Renal cysts and diabetes syndrome	Pancreas atrophy, diabetes, genital abnormalities	Unilateral kidney agenesis, hypoplasia, cortical atrophy, interstitial fibrosis, renal cysts	AD (137920)	<i>TCF2</i>
Renal dysplasia, retinal pigmentary dystrophy, cerebellar ataxia, and skeletal dysplasia (Mainzer–Saldino syndrome)	Retinal dysplasia, cerebellar hypoplasia, ataxia, hepatic fibrosis, skeletal anomalies, cone-shaped epiphyses	Renal dysplasia, hydronephrosis, megabladder, megaloureter	AR (266920)	
Renal dysplasia–limb defects (Ulbright)	Mesomelic bony dysplasia, hypoplasia of radius and tibia, characteristic facial appearance	Renal dysplasia	AR (266910)	
Roberts (SC phocomelia)	Tetraphocomelia, cleft lip/palate, severe psychomotor retardation, lethal; chromosomes with premature centromere separation	Renal dysplasia or agenesis, horseshoe kidney, hydronephrosis, polycystic kidney	AR (268300)	<i>ESCO2</i>
Short rib–polydactyly, type II (Majewski)	Median cleft lip; preaxial and postaxial polydactyly; short ribs and limbs; disproportionate shortening of tibia; anomalies of the genitalia, larynx, epiglottis and viscera, pachygyria, lethal	Renal dysplasia, polycystic kidneys, glomerular and renal tubular cysts	AR (263520)	<i>NEK1</i>
Short rib–polydactyly, type I (Saldino–Noonan)	Short limbs; metaphyseal dysplasia; defective ossification of calvarium, vertebrae, pelvis, carpals, and tarsals; trident pelvis; cardiac anomalies; GI atresia; genital anomalies; lethal	Renal dysplasia, polycystic kidneys	AR (263530)	
Smith–Lemli–Opitz	Cerebellar hypoplasia, mesomelic dysplasia, heart and eye anomalies, polydactyly, male pseudohermaphroditism, lethal	Renal dysplasia, hypodysplasia	AR (270400)	<i>DHCR7</i>

AD, autosomal dominant; AR, autosomal recessive.

5. Consider CT and MRI to define the anatomy of the kidney and contiguous structures
6. Banded karyotype for anomalies, abnormal growth, microcephaly, or developmental delay associated with chromosomal disorders in renal dysplasia
7. Voiding cystourethrogram

**62.4.4.2 Pathogenesis.** There are two basic processes that are believed to give rise to renal dysplasia. First, the development of the kidney from a few cells to a mature organ of a million nephrons requires a significant degree

of cell proliferation in nephrogenesis with a controlled balance of apoptosis in cells that need to be deleted. In dysplasia, there is upregulation of proliferation in dysplastic epithelia (which has a role in cyst development), and an excess of apoptosis in adjacent mesenchyme (which may be responsible for involution of dysplastic kidneys before or after birth) (91). Second, there is a disorder in the process of differentiation of renal precursor cells, which is still being clarified. Many genes have been identified, but their interactions in developmental pathways are still being studied. For example, Wilms tumor-1

**TABLE 62-9 Disorders Associated with Polycystic and Multicystic Kidneys, Including Disorders with Renal-Hepatic-Pancreatic Dysplasia**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Acrorenal–mandibular	Split hand/foot; genital, vertebral, rib and uterine anomalies	Renal agenesis, ureteral anomalies, cystic kidney, renal dysplasia	AR (200980)	
Asplenia with cardiovascular anomalies	Bilateral right or left embryonic primordia, asplenia, polysplenia, complex heart anomalies, situs inversus	Renal dysplasia, cortical cysts	AR (208530)	
Branchio–oto–renal (Melnick–Fraser)	Mixed hearing loss, Mondini cochlear malformation, pinnae anomalies, branchial cleft fistula, preauricular pits	Cystic dysplastic kidneys, renal agenesis, ectopia, ureteral anomalies	AD (113650)	<i>EYA1</i> <i>SIX1</i> <i>SIX5</i>
Campomelia, Cumming type	Severe shortening and bowing of long bones, cervical lymphocele, vertebral anomalies, cystic dysplasia of liver and pancreas, shortgut, polysplenia, pulmonary hypoplasia, other anomalies	Renal dysplasia, polycystic kidneys	AR (211890)	
Carnitine palmitoyltransferase deficiency, lethal neonatal	Dysmorphic face, cardiomegaly, respiratory failure, hepatomegaly, long digits, hypotonia, hypoglycemia	Enlarged polycystic kidneys, dysplastic renal parenchyma, lipid accumulation in kidney, especially proximal convoluted tubules, double ureters	AR (608836)	<i>CPT2</i>
Fryns	Neonatal lethal; diaphragmatic defects; distal digital hypoplasia; distinct facial features; pulmonary hypoplasia; eye, brain, and other anomalies	Renal dysplasia, cortical cysts	AR (229850)	
Glutaric acidemia, type II	Multiple acyl-CoA dehydrogenase deficiency, cerebral dysplasia, fatty liver, biliary dysgenesis, pancreatic dysplasia, Potter facies	Renal dysplasia, multicystic kidneys	AR (231680)	<i>ETFA</i> <i>ETFB</i> <i>ETFDH</i>
Hutterite cerebro–osteonephrodysplasia	Short stature with mild spondylorhizomelic dysplasia, failure to grow, severe mental retardation, postnatal microcephaly, seizures	Terminal nephrotic syndrome, nephrosis, proteinuria, end-stage renal disease	AR (236450)	
Jeune (asphyxiating thoracic dystrophy)	Small, bell-shaped thorax; pulmonary hypoplasia, polydactyly, variable rhizomelic limb shortening, trident pelvis, biliary dysgenesis, pancreatic dysplasia, other anomalies	Renal dysplasia, glomerulonephritis, juvenile nephrophthisis, stenosis of ureterovesical junction, hydroureters, multicystic kidneys	AR (208500)	
Joubert syndrome	Cerebellar vermic aplasia, ataxia, colobomata, Dandy–Walker malformation	Multicystic kidneys	AR (213300, 243910)	<i>INPP5E</i>
Meckel–Gruber	Occipital encephalocele, polydactyly, cleft lip/palate, microphthalmia, small or ambiguous genitalia, brain anomalies, biliary dysgenesis and pancreatic dysplasia	Renal dysplasia or hypodysplasia, ureteral hypoplasia or aplasia, hypoplastic bladder, urethral agenesis, renal cysts, hydroureter	AR (249000)	<i>MKS1</i>
Multinodular goiter, cystic renal disease, and digital anomalies	Multinodular goiter, triphalangeal thumbs, preaxial polydactyly of feet	Renal dysplasia, polycystic kidney	AD (138790)	
Orofaciodigital, type I	Lobulated tongue, median pseudocleft of lip, cleft palate, hypoplastic alae nasi, digital anomalies, mental impairment	Adult-onset polycystic kidneys	XLR (311200)	<i>CXORF5</i>

**TABLE 62-9 Disorders Associated with Polycystic and Multicystic Kidneys, Including Disorders with Renal-Hepatic-Pancreatic Dysplasia—cont'd**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Polycystic kidney, autosomal dominant	Hepatic cysts (hepatic fibrosis is unusual), mitral valve prolapse (25%), berry aneurysms of cerebral (10–36%) and abdominal vessels, cysts in pancreas, ovaries, lungs and other, diverticulitis	Cystic disease of renal medulla and corticomedullary nephrons and collecting tubules	AD (173900)	<i>PKD1</i> <i>PKD2</i>
Polycystic kidney, autosomal recessive	Hepatic fibrosis, biliary dysgenesis, pancreatic dysplasia	Medullary ductal ectasia, cortical cysts	AR (263200)	<i>PKHD1</i>
Polycystic kidney disease, Potter type I, with microbrachycephaly, hypertelorism and brachymelia	Microbrachycephaly, hypertelorism, brachymelia and distinctive facial features	Polycystic kidney disease, with cortical cysts and medullary ductal ectasia (Potter type I)	AR (263210)	
Senior-Loken (renal dysplasia-retinal aplasia)	Pigmentary retinal dysplasia, hypotonia, seizures, hearing loss, mental retardation	Renal dysplasia, juvenile nephrophthisis, medullary cystic disease	AR (266900)	<i>NPHP1</i>
Short rib polydactyly, type II (Majewski)	Median cleft lip; pre/postaxial polydactyly; short ribs and limbs; genital, laryngeal, epiglottic and visceral anomalies, pachygyria, biliary dysgenesis; pancreatic dysplasia; lethal	Renal dysplasia, multicystic kidneys, glomerular and renal tubular cysts	AR (263520)	<i>NEK1</i>
Short rib polydactyly, type I (Saldino-Noonan)	Phocomelia; metaphyseal dysplasia; defective ossification of calvarium, vertebrae, pelvis, carpal and tarsal bones; cardiac, GI and GU anomalies; biliary dysgenesis; pancreatic dysplasia; lethal	Renal dysplasia, multicystic kidneys	AR (263530)	
Trisomy 9	Potter sequence, cleft palate, joint immobility, biliary dysgenesis, pancreatic dysplasia	Renal dysplasia, multicystic kidneys	Chromosomal	
Tuberous sclerosis	Hypopigmented macules, adenoma sebaceum, retinal and brain tumors, seizures, mental retardation	Renal angiomyolipomas (70%), renal epithelial cysts (20–30%), oncocytoma, renal cell carcinoma, polycystic kidney disease	AD (191100)	<i>TSC1</i> <i>TSC2</i>
Von Hippel-Lindau	Retinal angiomas, cerebellar hemangioblastomas	Renal cysts, renal cell carcinoma (40%), bladder papillomas	AD (193300)	<i>VHL</i>
Zellweger syndrome	Death in early infancy, hypotonia, seizures, biliary dysgenesis, peroxisomal enzyme deficiency of dihydroxyacetonephosphate (DHAP) acyltransferase	Kidney with subcortical cysts, hydronephrosis, multicystic kidney	AR (214100)	<i>PEX 1-3,5,6,10, 12-14,16, 19,26</i>

AD, autosomal dominant; AR, autosomal recessive; XLR, X-linked recessive.

(WT1) is involved in mesenchymal-epithelial transformation and podocyte differentiation, and has a negative interaction with PAX2 (92,93). Of note, mutations in WT1 lead to the development of nephrogenic rests, an abnormal structure in the kidney that is formed by failure of the mesenchymal tissue to differentiate into nephrons; they are associated with the development of Wilms tumor (94). Nephrogenic rests are rarely seen in normal kidneys after 1 year of age, but are found in nearly all patients with multifocal or bilateral Wilms tumor and in 30% of children with sporadic Wilms tumor (95).

Homozygous mutations in the Wilms tumor suppressor gene (*WT1*) are found in 18% of Wilms tumors (96–98).

**62.4.4.3 Genetics.** There is etiologic heterogeneity for renal dysplasia, as is evident in Tables 62-6–62-9. Familial recurrence due to all patterns of inheritance has been reported for isolated renal dysplasia and when associated with MCA syndromes (Tables 62-6–62-9). Teratogenic agents have been associated with renal dysplasia or cystic changes in human and experimental animal models after in utero exposure to alcohol, abnormal metabolites

because of maternal diabetes, maternal rubella, thalidomide, hypoxia, and ACE inhibitors.

Prenatally diagnosed chromosomal abnormalities in renal dysplasia occur in 10.3–28.5% of fetuses (Table 62-10). Conversely, 35% of individuals with chromosomal disorders have renal anomalies, most commonly renal dysplasia and micropolycystic kidneys.

Renal ultrasound examinations of first-degree and, when indicated, second-degree relatives are necessary to exclude variable expression of autosomal dominant disorders, particularly hereditary renal adysplasia. Using renal ultrasound results from parents and sibs of 41 probands with bilateral renal agenesis or cystic dysplasia or both, Roodhooft and colleagues (40) determined a 9% risk for related urogenital anomalies and a 4.4% risk for renal anomalies. Perinatal lethal renal disease is associated with a 3.6% recurrence

risk for sibs and a 0.2% risk for first cousins. Empiric recurrence risks can be used for families with a proband affected with renal dysplasia after excluding monogenic, syndromic, and chromosomal disorders. Affected individuals or obligate heterozygotes for hereditary renal dysplasia have an empiric recurrence risk of 15–20% for having a child with unilateral or bilateral renal agenesis.

There are several autosomal dominant syndromes associated with dysplasia: renal coloboma syndrome (PAX2), renal cysts and diabetes syndrome (HNF1B), branchio-oto-renal syndrome (EYA1, SIX1), and Townes–Brocks syndrome (SALL1).

**62.4.4.4 Prenatal Diagnosis.** Prenatal diagnosis of renal dysplasia has been successful using ultrasound imaging and, in selected cases, maternal serum alpha-fetoprotein screening (99). The classical antenatal presentation of dysplastic kidneys is large bright kidneys, with or without cortical cysts on the 20 week ultrasound. The degree of abnormality depends on the severity of the following variables: abnormality of size, brightness, visibility and number of cysts, amniotic fluid and abnormalities in other organ systems. In the multicystic dysplastic kidney, there are multiple thin-walled cysts at 20 weeks, which do not connect, and are distributed randomly throughout the kidney; often a renal pelvis or ureter may not be seen (64). Exclusion of associated structural anomalies and karyotype determination is recommended when renal malformations are identified. Of the fetuses identified by ultrasound as having one kidney with multicystic dysplasia, 40% have contralateral renal anomalies, 20% have bilateral multicystic dysplasia, 10% have contralateral renal agenesis, and 10% have contralateral hydronephrosis, most commonly due to ureteropelvic junction obstruction.

Chromosome abnormalities in fetuses identified to have cystic dysplastic kidneys on ultrasound scans vary, depending on the presence of associated structural anomalies (Table 62-10). The fetal risk for chromosomal abnormalities with unilateral multicystic kidneys is 2% and bilateral involvement 4%, if this is an isolated finding. When associated structural anomalies are apparent on ultrasound imaging, there is a risk for chromosomal aneuploidy of 44% for unilateral renal findings and 33% for bilateral renal abnormalities.

**62.4.4.5 Management and Outcome.** Many dysplastic kidneys involute over time, including before birth (100,101). In this case, the prognostic indicators are the presence of abnormalities and compensatory hypertrophy of the contralateral kidney (102). Fetal prognosis is dependent on the extent of renal involvement, the amount of amniotic fluid, and the associated structural malformations, as well as the underlying diagnosis. Progressive deterioration in renal function is the usual clinical course when dysplastic changes are bilateral or when contralateral renal agenesis or hypodysplasia is present. These children exhibit urinary concentrating defects, metabolic

acidosis, and growth failure. However, affected infants may experience improvement in renal function through normal physiologic adaptation to postnatal life during infancy with later gradual deterioration in function. Prophylactic antibiotics should be started at birth to prevent urinary tract infections, until the presence of vesicoureteral reflux and other ureteral abnormalities have been ruled out by further imaging. Radionuclide scan can be considered to evaluate split excretory function from either kidney.

Unilateral renal dysplasia may remain asymptomatic. Operative removal of unilateral dysplastic kidney may not be necessary in the absence of clinical symptomatology (e.g. pain, mass effect, or hypertension) (89). Tumors have infrequently been reported to arise in the cysts of the dysplastic kidneys (89), but the risk for development of Wilms tumor in multicystic, dysplastic kidneys has been overemphasized (90).

### 62.4.5 Ureteral Abnormalities

Agenesis of the ureters is not usually found in the absence of other urinary tract malformations. Renal agenesis is frequently associated with partial or complete agenesis of the ureters. Disorders such as sirenomelia, associated with caudal dysplasia, frequently have ureteral agenesis or abnormalities.

Duplication of the ureters is common, with a prevalence of 1:50 to 1:300 (18). Duplication may be complete with two ureters extending from the renal pelvis to the bladder, or the ureters may unite before entering the bladder. Unilateral duplication is five to six times more common than bilateral duplication. Ureteral anomalies may remain asymptomatic, presenting at autopsy, or can present with symptoms resulting from obstruction: infection, hydronephrosis, or ureterocele.

**62.4.5.1 Pathogenesis.** The ureters are derivatives of the ureteric buds, originally part of the distal mesonephric ducts, which open into the anterior portion of the hindgut, forming the cloaca. The terminal portions of both mesonephric ducts are incorporated into the endodermal vesicoureteral primordium, forming the vesical trigonum. Abnormal division during ureteric bud formation is postulated as the pathogenetic mechanism for duplication of the ureters, which occurs during developmental weeks six through 11. The point of origin of the ureteric bud becomes the ureteral orifice in the urinary bladder. Abnormal placement of the point of origin will lead to ureteral ectopia.

**62.4.5.2 Genetics.** Ureteral anomalies clearly have a hereditary basis, especially in the presence of associated anomalies (Tables 62-11 and 62-12; see also Tables 62-2–62-9). There is suggestion in the medical literature that isolated ureteral anomalies have a hereditary basis; however, information on empiric recurrence risk for bifid (double) ureters is limited. Atwell et al. (103) report a high frequency of unilateral or bilateral bifid

ureters among sibs and parents of 30 probands presenting clinically with this finding. When a bifid pelvicalyceal system is included, 20 of the 30 families studied have affected first-degree relatives. Male-to-male transmission is observed, suggesting autosomal dominant inheritance with variable expression. Renal ultrasound imaging will simplify diagnosis of severe ureteral anomalies among first-degree relatives, but will not identify duplicated ureters that are not dilated.

Duplication of the ureter is found as a nonobligatory feature in a number of syndromes, chromosomal abnormalities, and inherited disorders. Because of the high prevalence of ureter duplication as an isolated malformation, this finding may not be helpful with reference to syndrome diagnosis. Genetic disorders commonly associated with ureteral abnormalities include ectrodactyly–ectodermal dysplasia–clefting (EEC) syndrome, Kaufman–McKusick syndrome, von Mayer–Rokitansky–Kuster (MRK) anomaly, hypertelorism–microtia–clefting syndrome, restrictive dermatopathy, hereditary renal adysplasia, infants of diabetic mothers, as well as other malformation sequences, chromosomal abnormalities, and monogenic disorders listed in Tables 62-2 and 62-3.

Ureterocele, a saccular out-pouching of the distal ureter into the urinary bladder, has been reported in monozygotic and dizygotic twins, in sibs, and in apparent parent–child inheritance. Ureteroceles are very frequently associated with duplications of the kidney and ureter.

### 62.4.6 Bladder

Major anomalies of the bladder are frequently associated with other malformations including exstrophy of the bladder, exstrophy of the cloaca, anomalies of the urachus, and prune-belly anomaly (discussed later).

Agenesis of the bladder is an almost constant feature in sirenomelia. Other anomalies of the urinary and genital system are usually present as well, including absence of the ureters and uterus, or abnormal insertion of the ureters into the urethra or uterus. A hypoplastic bladder is expected in association with bilateral renal agenesis or other renal anomalies that prevent urine production and delivery to the bladder.

Bladder exstrophy, where the bladder is open anteriorly, is due to the lack of abdominal wall closure. It is often associated with epispadias and separation of the pubic rami. Numerous familial cases have been described. Bladder exstrophy can be part of the omphalocele–exstrophy–imperforate anus–spinal defects (OEIS) complex.

Abnormal configuration of the bladder may be seen in bladder diverticulum, persistence of the urachus, and incomplete or complete duplication of the bladder. True diverticulae are evaginations of the bladder wall. They may arise as herniations of the bladder wall because of distal obstruction or as intrinsic defects in bladder musculature. A diverticulum of the dome of the bladder may

**TABLE 62-11 Disorders with Abnormalities of the Urethra**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Amastia, bilateral with ureteral triplication	Anastia, unusual facies, hemivertebrae, mitral valve prolapse, umbilical hernia, syndactyly	Ureteral triplication, hydronephrosis	AD (104350)	
Aphalangy with hemivertebrae	Aphalangy, hemivertebrae, urogenital–intestinal dysgenesis, anal atresia, persistent cloaca	Urethral atresia, absent ureters, bilateral renal agenesis	AR (207620)	
Bardet–Biedl syndrome	Obesity, pigmentary retinopathy, polydactyly, hypogenitalism	Ectopic urethra, cystic kidneys	AR (209900)	<i>BBS1-15</i>
Caudal dysplasia (caudal regression)	Sacral agenesis/hypoplasia, lower limb and other skeletal anomalies, anal atresia, genital anomalies	Urethral, bladder and ureteral anomalies, renal agenesis or dysplasia	Heterogeneous, maternal diabetes	
Chromosomal abnormalities	See <a href="#">Table 62-2</a>			
Cloacal exstrophy	Persistent cloaca, exstrophy of cloaca, failure of fusion of genital tubercles, omphalocele, vertebral defects, spina bifida cystica, abnormal internal and external genitalia	Duplication of urethra; urethral and ureteral anomalies, exstrophy of bladder, renal dysplasia, renal agenesis, renal ectopy		
Conjoined twins	Urinary tract anomalies are most common in iliothoracopagus, ischiopagus, diprosopus, dicephalus, dipygus conjoined twins	All urinary anomalies may occur	Unknown	
Diabetes, maternal	Caudal regression, neural tube defects, heart and other anomalies	Urethral, bladder, and ureteric anomalies; renal agenesis; urethral atresia	Metabolic teratogenicity due to maternal diabetes	
Distal obstructive uropathy polydactyly	Polydactyly, oligohydramnios, stillbirth	Posterior urethral valve with hydronephrosis, hydroureter, dilated bladder	Unknown	
Early amnion rupture (ADAM, amniotic bands)	Digital and limb amputations, ring constrictions, facial clefts, other anomalies	Urethral duplication; other urethral anomalies; renal agenesis, dysplasia, ectopy; ureteral anomalies	Sporadic	
Facial–skeletal–genital, Rippberger type	Facial dysmorphism, neurosensory deafness, normal intelligence	Recurrent urethral strictures, urinary tract infections	Unknown	
Hand–foot–uterus (hand–foot–genital)	Hypoplasia of the thumbs and great toes, duplication of female internal genitalia, chordee and hypospadias in males	Duplication of urethra, ectopic ureteral orifices, intravaginal urethra, hydronephrosis, epididymal cyst	AD (140000)	<i>HOXA13</i>
McKusick–Kaufman	Hydrometrocolpos, transverse vaginal membrane, vaginal septum, postaxial polydactyly, cardiac anomalies, hypospadias	Hydroureter, ureteral duplication, urogenital sinus, ectopic urethra	AR (236700)	<i>BBS6</i>
Limb–body wall disruption	Lateral body wall deficiency, neural tube defect, severe scoliosis, absent or abnormal limb(s)	Urethral duplication or atresia; bladder exstrophy, renal agenesis, dysplasia fusion or ectopy; ureteral anomalies	Sporadic	
Meckel–Gruber	Occipital encephalocele, polydactyly, cleft lip/palate, microphthalmia, small or ambiguous genitalia, brain anomalies, biliary dysgenesis, pancreatic dysplasia	Renal dysplasia or hypodysplasia, ureteral hypoplasia or aplasia, hypoplastic bladder, urethral agenesis	AR (249000)	<i>MKS1</i>
Michels (oculopalatoskeletal)	Cleft lip/palate, deafness, blepharophimosis, anterior chamber eye anomalies, skeletal anomalies	Urethral and ureteral	AR (257920)	
Neurofibromatosis 1	Café-au-lait spots, neurofibromas, Lisch nodules, axillary freckling, local bony overgrowth, macrocephaly	Neurofibromas of the urethra, bladder, or ureter; renal artery stenosis; hydronephrosis	AD (162200)	<i>NF1</i>

**TABLE 62-11 Disorders with Abnormalities of the Urethra—cont'd**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Potter sequence	Craniofacial and skeletal compression deformities from oligohydramnios	Bilateral renal agenesis, aplasia, hypoplasia or dysplasia; urethral agenesis; posterior urethral valves	Heterogeneous	
Prune-belly syndrome	Deficient abdominal muscle, urinary obstruction/distention, undescended testes malrotation of the gut, clubfoot, limb reduction anomalies	Posterior urethral valves, urethral atresia, ureteral duplication, bladder distension, hydronephrosis, renal dysplasia	Heterogeneous (100100)	
Renal adysplasia	Anomalies of internal genitalia; occasional anomalies of anus, heart, spine, hands, and feet	Renal agenesis, hypoplasia, or dysplasia; ureteral and urethral anomalies	AD (191830)	<i>RET</i> <i>UPK3A</i>
Sacral defect with anterior meningocele (sirenomelia)	Fusion of lower limbs, sacral agenesis, anal atresia, uterine/vaginal anomalies, cardiac defects	Urethral atresia, ectopic urethra, posterior urethral valves, renal agenesis, cystic dysplasia, horseshoe kidneys, ureteral and bladder anomalies	AD (600145)	<i>VANGL1</i>
Townes–Brocks	Anal anomaly, imperforate anus, bifid or triphalangeal thumbs, features of hemifacial microsomia	Renal agenesis or dysplasia, ureteral and urethral anomalies	AD (107480)	<i>SALL1</i>
Urofacial syndrome (Ochoa)	“Inversion” of facial expression when laughing	Neuropathic bladder, posterior urethral valves, hydroureter	AR (236730)	<i>HPSE2</i>
Urorectal septum malformation	Ambiguous genitalia, Müllerian anomalies, persistent cloaca, imperforate anus, vaginal atresia	Urethral agenesis, renal agenesis or dysplasia, bladder dilation	Sporadic, maternal diabetes in some patients	
VACTERL association	Vertebral defects, anal atresia, cardiac malformation, tracheoesophageal fistula, radial ray hypoplasia/aplasia, limb anomalies	Renal agenesis, hypoplasia, or cystic dysplasia; ureteral and urethral anomalies	Sporadic (192350)	
Williams syndrome	“Elfin” facies, stellate iris, short stature, heart defects, hypercalcemia	Urethral stenosis, solitary kidney, pelvic kidney	AD (194050)	7q11.23 deletion

AD, autosomal dominant; AR, autosomal recessive.

represent persistence of the urachus. Lateral diverticulae may represent incomplete partition of the bladder and may or may not be associated with duplication of the urethra, genitalia, and rectum. Clinical presentation of bladder diverticulae is most commonly recurrent urinary tract infections, due to incomplete emptying with voiding. Diverticulae of the bladder may occur in association with diverticulae of the intestines, and with obstruction of the urethra due to prostatic hyperplasia or tumor, both of which have a familial predisposition.

Bladder diverticulae occur as a clinical feature of heritable disorders, particularly involving abnormal copper metabolism (i.e. cutis laxa, occipital horn syndrome, and Menkes syndrome). They can also occur in Ochoa syndrome, an autosomal dominant condition associated with neuropathic bladder, posterior urethral valves (PUVs), and hydroureter.

Congenital dilatation of the bladder, presenting in utero, has a number of etiologies. The obstruction is usually due to PUVs, particularly in males (see later

discussion). Deficiency of the abdominal musculature (prune-belly anomaly), ascites, hydroureter, and hydronephrosis are frequently associated anomalies. Bladder dilatation can result from neurologic impairments, including neural tube defects, mitochondrial myopathies, and agangliosis. Megacystis in the absence of recognized obstruction occurs in the megacystis–microcolon–hypo-peristalsis syndrome.

### 62.4.7 Urethral Agenesis and Atresia

Absence of the urethra is rare and reported predominantly in males. Congenital segmental urethral agenesis or atresia is more common than complete atresia. The level of obstruction is usually at the membranous urethra. Failure of formation of all or part of the urethra is an anomaly that is frequently associated with prune-belly syndrome (i.e. Eagle–Barrett syndrome).

**62.4.7.1 Clinical Features.** Presenting signs and symptoms of urethral agenesis or segmental absence include

**TABLE 62-12 Disorders Associated with Posterior Urethral Valves**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Amyloidosis, familial cutaneous	Amyloidosis, incontinentia pigmenti, failure to thrive, seizures, developmental delay, blindness	Urethral stricture	XLR (301220)	
Aphalangy with hemivertebrae	Aphalangy, hemivertebrae, urogenital–intestinal dysgenesis, anal atresia	Urethral atresia, absent ureters, bilateral renal agenesis	AR (207620)	
Caudal dysplasia (caudal regression)	Sacral agenesis/hypoplasia, lower limb and skeletal anomalies, anal atresia, genital anomalies	Urethral, bladder, and ureteral anomalies; renal agenesis or dysplasia	Heterogeneous, maternal diabetes in some patients	
Chromosomal abnormalities	See <a href="#">Table 62-2</a>			
Cloacal exstrophy	Persistent cloaca, exstrophy of cloaca, failure of fusion of genital tubercles, omphalocele, vertebral defects, spina bifida cystica, abnormal internal and external genitalia	Duplication of urethra, urethral and ureteral anomalies, exstrophy of bladder, renal dysplasia, renal agenesis or ectopy	Sporadic	
Diabetes, maternal	Caudal regression, neural tube defects, heart and other anomalies	Urethral, bladder, and ureteric anomalies; renal agenesis with caudal regression	Metabolic teratogens	
Distal obstructive uropathy polydactyly	Polydactyly, oligohydramnios, stillbirth	Posterior urethral valves with hydronephrosis, hydroureter, dilated bladder	Unknown	
Facial–skeletal–genital, Rippberger type	Facial dysmorphism, neurosensory deafness, normal intelligence	Recurrent urethral stricture, urinary tract infections	Unknown	
Hand–foot–uterus	Hypoplasia of thumbs and great toes, duplication of female internal genitalia; chordae and hypospadias in males	Ectopic ureteral orifices, intravaginal urethra, hydronephrosis, epididymal cyst, posterior urethral valves	AD (140000)	<i>HOXA13</i>
Limb–body wall complex (lateral body wall defect)	Lateral body wall defects, limb reduction anomalies, neural tube defects, heart and other anomalies	Urethral atresia or duplication (with bladder exstrophy); renal agenesis, dysplasia, fusion, or ectopy; ureteral anomalies, posterior urethral valves	Sporadic	
McKusick–Kaufman	Hydrometrocolpos, transverse vaginal membrane, vaginal septum, postaxial polydactyly, cardiac anomalies, hypospadias	Hydroureter, ureteral duplication, ectopic urethra, urogenital sinus, posterior urethral valves	AR (236700)	
Michels (oculopalatoskeletal)	Cleft lip/palate, deafness, blepharophimosis, anterior chamber eye anomalies, skeletal anomalies	Urethral and ureteral anomalies	AR (257920)	
Neurofibromatosis 1	Café au lait spots, neurofibromas, Lisch nodules, axillary freckling, local bony overgrowth, macrocephaly	Neurofibromas of the urethra, bladder, or ureter; renal artery stenosis; hydronephrosis, posterior urethral valves	AD (162200)	<i>NF1</i>
Potter sequence	Facial and skeletal deformations resulting from oligohydramnios, pulmonary hypoplasia	Bilateral renal agenesis, hypoplasia, or dysplasia; urethral agenesis; posterior urethral valves	Heterogeneous	
Prune-belly syndrome	Deficient abdominal muscles, urinary obstruction/distention, undescended testes, malrotation of the gut, clubfeet, limb reduction anomalies	Posterior urethral valves, urethral atresia, ureteral duplication, hydronephrosis, bladder distension, renal dysplasia	Heterogeneous (100100)	
Renal adysplasia	Anomalies of internal genitalia; occasional anomalies of anus, heart, spine, hands, and feet	Renal agenesis, hypoplasia, or dysplasia; ureteral and urethral anomalies	AD (191830)	<i>RET</i> <i>UPK3A</i>

**TABLE 62-12 Disorders Associated with Posterior Urethral Valves—cont'd**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Rubinstein–Taybi	Broad thumbs and toes, distinctive facial features, mental retardation, microcephaly, cryptorchidism, small phallus	Posterior urethral valves, absent or extra kidneys, ureteral anomalies, double renal pelvis, renal calculi, abnormal bladder shape	AD (180849)	<i>CREBBP</i>
Sacral defect with anterior meningocele (sirenomelia)	Fusion of lower limbs, sacral agenesis, anal atresia, uterine/vaginal anomalies, cardiac defects	Urethral atresia, ectopic urethra, posterior urethral valves, renal agenesis, cystic dysplasia, ureteral and bladder anomalies	AD (600145)	<i>VANGL1</i>
Townes–Brocks	Anal anomaly, imperforate anus, bifid or triphalangeal thumbs, features of hemifacial microsomia	Renal agenesis, ureteral and urethral anomalies	AD (107480)	<i>SALL1</i>
Urofacial syndrome (Ochoa)	“Inversion” of facial expression when laughing	Neuropathic bladder, posterior urethral valves, hydroureter	AR (236730)	<i>HPSE2</i>
Urorectal septum malformation	Ambiguous genitalia, Müllerian anomalies, persistent cloaca, imperforate anus, vaginal atresia	Urethral agenesis, renal agenesis or dysplasia, bladder dilation, posterior urethral valves	Sporadic, infant of diabetic mother in some cases	
VACTERL association	Vertebral defects, anal atresia, cardiac malformation, tracheoesophageal fistula, radial ray hypoplasia/aplasia, limb anomalies	Renal agenesis, hypoplasia, or cystic dysplasia; ureteral and urethral anomalies	Sporadic (192350)	

AD, autosomal dominant; AR, autosomal recessive; XLR, X-linked recessive.

abdominal distension due to enlarged bladder or urinary ascites, laxity of abdominal musculature, bilateral cryptorchidism, oligohydramnios, respiratory insufficiency, failure to pass urine, or evidence of urinary fistulae such as a patent urachus.

Associated anomalies can include megacystis, hydroureter, hydronephrosis, dysplastic kidneys, undescended testes, and pulmonary hypoplasia. Urachal, cloacal, urethrorectal, urethropenile, urethroscrotal, or vesicovaginal fistulae are frequently present. Anal atresia or ectopic anus and abnormal development of the prostate, urinary tract musculature, and gubernaculum are common. Hypoplastic abdominal musculature is present in prune-belly syndrome. Loops of bowel protruding under the thin abdominal wall give the characteristic prunelike appearance. Bladder distension can lead to obstruction of the umbilical arteries with lower limb ischemia, hypoplasia, or transverse reduction defects. Affected females may also have bicornuate or duplicated uterus, vaginal atresia, clitoral hypertrophy, anal atresia, and upper urinary tract anomalies.

**62.4.7.2 Genetics.** Disorders associated with urethral agenesis and atresia are listed in Table 62-11. When a specific disorder is not identified, recurrence risk for urethral atresia appears to be low.

**62.4.7.3 Diagnosis and Differential Diagnosis.** Abdominal distension with abdominal muscular hypoplasia so that the loops of bowel can be readily seen is pathognomonic for the prune-belly syndrome. Other frequent findings include features of the Potter sequence due to oligohydramnios, unless a urethral-visceral fistula or a patent urachus is present. Marked posterior urethral dilation, secondary to the obstruction at the membranous urethra, results in the typical appearance on

ultrasound of a dumbbell-shaped bladder or “keyhole sign,” identifiable both in utero and postnatally.

Diagnosis is often possible by fetal ultrasound. The differential diagnosis includes other urethral abnormalities resulting in severe obstruction, including PUVs and urethral duplication.

**62.4.7.4 Prenatal Diagnosis.** Prenatal detection by ultrasound imaging of urinary tract obstruction associated with megacystis, dumbbell-shaped bladder, increased abdominal circumference, and oligohydramnios suggest the possibility of urethral agenesis or atresia.

Detection of recurrence of significant urethral anomalies with subsequent pregnancies is possible with diagnostic fetal ultrasonography. Fetal ultrasonographic evaluation for evidence of urinary tract obstruction is recommended at 16–18, 24 and 32 weeks of pregnancy, since obstruction can present later in pregnancy. Severe obstruction may be diagnosable with high-level ultrasonography as early as 12–14 weeks of pregnancy.

**62.4.7.5 Management.** In utero urinary decompression with a vesicoamniotic shunt can be performed in a fetus with urethral atresia, but should only be attempted if there is residual renal function. Exclusion of underlying syndromic, chromosomal, and teratogenic etiologies associated with a poor prognosis is recommended before aggressive treatment. In the newborn with oligohydramnios, pulmonary insufficiency is frequently present, and usually requires aggressive management. Diagnostic investigations are directed toward determination of the cause of the obstruction and evidence of residual renal function.

Urinary diversion or vesicostomy may be necessary before reconstruction of the urethra. In prune-belly

syndrome, surgical management ultimately includes abdominoplasty, bilateral orchiopexy, reduction cystoplasty, and selective ureteral reconstruction and reimplantation. Kidney transplantation and the use of the bowel for partial reconstruction of the ureters and/or urinary bladder have improved the outcome in severe obstructive uropathy.

### 62.4.8 Duplication of the Urethra

Duplication of the urethra may be complete, with two separate external meati, or partial, with a variable outlet of the accessory urethra. Urethral duplications are subclassified anatomically (e.g. epispadias, hypospadias, and Y-type accessory channel opening into the perineum or anal canal) (104). The etiology of these conditions is unknown. Urethral duplication has occurred in males with VACTERL association and in males with PUVs.

### 62.4.9 Posterior Urethral Valves

PUVs are found in males, masculinized females, and, rarely, in normal females. The incidence is estimated to be 1 in 5000–8000 male infants. PUVs are recognized to be the most common cause of obstructive uropathy that may lead to renal failure in childhood. The “valves” are actually tissue folds located in the posterior urethra that functionally obstruct urine outflow.

**62.4.9.1 Clinical Features.** The age of presentation, clinical symptoms, and ease of diagnosis are variable and depend on the severity of obstruction. In regions of the world where prenatal ultrasonography is routine, the majority of these infants are detected in utero. Prior to the widespread use of prenatal ultrasonography, it was estimated that one-third to half of individuals with PUVs presented within the first 3–6 months of life and the majority within the first year of life.

Commonly presenting symptoms in those not diagnosed prenatally are abdominal mass (38–53%), oligohydramnios (32%), failure to grow (18–40%), sepsis or urinary tract infections (20%), or a weak urinary stream (14%). Associated anomalies in the urinary tract system include a thickened, trabeculated bladder, dysfunctional voiding, ureterovesical junction obstruction, vesicoureteral reflux, hydronephrosis, and renal dysplasia. Severe oligohydramnios is associated with pulmonary hypoplasia and respiratory insufficiency postnatally.

Valvular obstruction results in incomplete emptying of the bladder. Back pressure leads to dilation of the posterior urethra. The bladder neck and detrusor musculature hypertrophy and thicken. The bladder may become trabeculated and sacculated with thickened walls. Urinary ascites can develop by transudation of urine through small bladder perforations, fistulae with surrounding organs, or a patent urachus. The ureters are dilated in 70% of cases with PUVs. Functional obstruction of the ureterovesical junction can occur secondary

to thickened detrusors. Vesicoureteral reflux is present in 45% of cases with PUVs and is unilateral in 17%. Reflux, especially when associated with urinary tract infections, contributes to more rapid loss of renal function. Dysplasia of the kidneys can occur secondary to obstruction and from associated anomalies of the metanephric buds (4).

**62.4.9.2 Genetics.** Disorders of multiple congenital anomalies associated with PUVs are listed in Table 62-12. The majority of individuals with PUVs are otherwise normal. Isolated PUVs appear to have a recurrence risk of 2–6% (4).

**62.4.9.3 Diagnosis and Differential Diagnosis.** Initial evaluation of an infant with bladder obstruction includes determination of renal function and electrolyte balance. Diagnosis of PUVs is made with a voiding cystourethrogram and by urethral endoscopy. There is an appearance of elongation and marked dilation of the posterior urethra with a sharp cutoff distal to the verumontanum and a narrowed distal urethral segment. Diagnostic evaluation of the upper urinary tract system is indicated with ultrasound and renography with radioisotopes. CT urography is less useful in the newborn and others with decreased concentrating ability and uremia.

**62.4.9.4 Prenatal Diagnosis.** Urinary tract obstruction is diagnosed with increasing frequency during the fetal period by ultrasound. Fetal PUVs appear on ultrasound scans as a dilated bladder sometimes with a dilated posterior urethra (i.e. keyhole sign), variable dilatation of the upper urinary tract, and oligohydramnios, the severity of which are dependent on the degree of obstruction. The risk for chromosomal aneuploidy after identification of bilateral hydronephrosis, which can be due to causes other than PUV, is 4% when it is an isolated finding, and 31% when there are associated structural anomalies (Table 62-10). Prenatal diagnosis with fetal sonograms at 18, 24, and 32 weeks of pregnancy can detect occurrence of bladder enlargement and incomplete emptying, hydroureter, pelvocaliectasis, and oligohydramnios. PUVs can also present postnatally; therefore, postnatal ultrasonographic evaluation and urethral endoscopy are indicated in suspicious cases.

**62.4.9.5 Management.** Management and treatment are dependent on the anomalies present and the degree of urinary tract obstruction. During pregnancy, in utero drainage of the obstructed fetal bladder may be performed at perinatal centers. Treatment is intended to prevent continued renal damage and complications of oligohydramnios. Before in utero intervention, it is imperative to determine if there is adequate residual renal function by measuring amniotic fluid electrolytes. Postnatally, primary ablation of the valves with transurethral fulguration is usually successful. When the anterior urethral lumen is too narrow for endoscopy, a temporary vesicostomy may be necessary. When renal impairment is present, upper tract drainage with cutaneous pyelostomy or high ureterostomy may be indicated,

with later reconstruction. Dialysis and renal transplantation may be necessary later in infancy, childhood, or adolescence.

Survival is dependent on the severity of the obstruction, the amount of residual renal function, and the presence of associated anomalies. Fetuses with severe oligohydramnios and renal dysplasia secondary to PUVs rarely survive the newborn period or are stillborn. There is increased mortality in infants presenting within the first 3 months of the newborn period because of renal dysplasia and insufficiency. In prenatally diagnosed cases with severe genitourinary abnormalities, 32% of fetuses die. Among those children presenting after 1 year of age, mortality is less than 10%. Mortality is higher in individuals with associated nonrenal congenital anomalies.

Studies of long-term outcome have identified three risk factors for late development of renal failure: (i) presentation before age 1 year, (ii) bilateral vesicoureteral reflux at the time of presentation, and (iii) daytime urinary incontinence at age 5 years. Long-term complications include recurrent urinary tract infection, persistent vesicoureteral reflux, and hydronephrosis; urinary incontinence after ablation of the PUVs; bladder dysfunction; polyuria; late onset of renal failure; infertility; and sexual dysfunction.

## 62.5 ERRORS OF MIGRATION AND POSITION

### 62.5.1 Horseshoe Kidney

Horseshoe kidneys are the most common type of fused kidneys, accounting for 90% (18). Horseshoe kidneys have been found by radiographs in 1 in 200 individuals and at postmortem examination in 1 in 450 individuals (18); the male to female ratio is 2–3:1. Fused kidneys are unable to ascend from the embryonic pelvic position; horseshoe kidneys have an equal amount of renal tissue on each side of the midline. Fusion is usually at the lower poles, and the ureters do not cross the midline before entering the renal sinuses.

**62.5.1.1 Clinical Features.** It is estimated that one-third of individuals with horseshoe kidneys remain asymptomatic (18). Horseshoe kidneys are found in asymptomatic individuals in the course of evaluations for associated structural anomalies, investigations for unrelated medical problems, or at abdominal operation.

The most common clinical symptoms are pain, hematuria, and urinary tract symptoms from obstruction of the ureters. Infants and children may present with a lower abdominal mass. In one study of individuals with horseshoe kidneys, 40% presented with ureteropelvic junction obstruction, 18% with renal stones, and 22% with urinary tract infection (105).

The calyces usually point posteriorly, with a vertical pelvic axis, because of failure of normal rotation. Hydronephrosis is the most commonly associated

genitourinary anomaly, being present in 45% of horseshoe kidneys. The hydronephrosis is associated with reflux in 59%, ureteral obstruction in 17%, and megaureter in 24%. Only 6.5% of the hydronephrosis is due to extrinsic ureteral compression. Other associated common genitourinary anomalies are hypospadias and cryptorchidism.

Nongenitourinary tract anomalies are present in one-third of individuals with horseshoe kidneys—79% of infants, 28% of children, and 4% of adults. Anomalies are found most frequently in the musculoskeletal, cardiac, and central nervous systems (89), and are associated with vertebral malformations, meningomyelocele, sacral agenesis, and anorectal atresia with fused kidneys.

**62.5.1.2 Genetics.** Horseshoe kidneys are usually sporadic or related to the underlying genetic, chromosomal, or syndromic disorder (Table 62-13). Familial recurrence has been reported, as has concordance in monozygotic twins.

Three embryologic explanations for renal fusion may account for horseshoe kidneys: (i) primary fusion at gestational weeks four to six may occur because of close proximity of the lower poles of the kidneys, leading to adhesion of parenchymal elements from the two nephrogenic cords, or development of a fused kidney from a single nephrogenic cord that interacts with separate ureteric buds arising from two wolffian ducts; (ii) secondary fusion may occur as late as gestational weeks seven to nine because of disruption of vascular blood supply or premature ablation of the polar arteries during upward migration, resulting in partial necrosis and subsequent fusion of the kidneys; (iii) usually the lower poles of the two kidneys fuse before crossing the iliac arteries at 7–9 weeks gestation. Normal renal ascent from the pelvic area is prevented when the fused kidneys reach the junction of the aorta and inferior mesenteric artery.

**62.5.1.3 Diagnosis and Differential Diagnosis.** Initial investigation with ultrasound can identify the basic renal anatomy, evidence of obstruction, and cystic dilation of the calyces (89). CT urography or MRI is especially helpful in defining the anatomy of the ureters and kidneys. Angiography to define the blood supply is important if surgery is anticipated. Radioisotope tests can be useful in the initial and follow-up evaluations of renal function. Retrograde pyelography may be necessary to determine the entire course of the ureters. Crossed fused renal ectopy, lump kidney, and pancake kidney can present as an abdominal mass with similar urinary tract anomalies. The structural difference is apparent on ultrasound scans.

**62.5.1.4 Prenatal Diagnosis.** Routine fetal sonogram does not consistently identify horseshoe kidneys in the fetus. Fetal horseshoe kidneys may be identified if there are renal anatomic anomalies (e.g. obstructed ureters, relatively low placement of the kidney in the pelvis, or cysts), other associated anomalies, or chromosomal disorders (e.g. Turner syndrome) present.

**62.5.1.5 Management.** Only rarely is death of individuals with horseshoe kidneys attributable to the renal

**TABLE 62-13 Disorders Associated with Horseshoe Kidneys, Renal Ectopy, and Fusion**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Acrorenal	Hypertelorism, micrognathia, minor skeletal anomalies, horseshoe kidney	Renal agenesis, crossed ectopia	?AD (102520)	
Asplenia with cardiovascular anomalies	Bilateral right or left embryonic primordia, asplenia, polysplenia, complex heart anomalies, situs inversus	Renal dysplasia, fused/ectopic kidneys, horseshoe kidneys	AR (208530)	
Beckwith–Wiedemann	Omphalocele, macroglossia, organomegaly, islet cell hyperplasia, adrenal cytomegaly, embryonic tumors, macrosomia	Nephromegaly, renal medullary dysplasia, Wilms tumor, nephrocalcinosis	AD (130650)	<i>CDKN1C</i> imprinting error, uniparental disomy, duplication, inversion or translocation of 11p15.5
Branchio–oto–renal	Mixed hearing loss, Mondini cochlear malformations, pinna anomalies, branchial cleft fistulas, preauricular pits	Renal dysplasia, agenesis, and ectopy; horseshoe kidneys, ureteral anomalies (but rarely duplications)	AD (113650)	<i>EYA1</i> <i>SIX1</i> , <i>SIX5</i>
Caudal dysplasia	Sacral agenesis/hypoplasia, lower limb and skeletal anomalies, anal atresia, genital anomalies	Renal dysplasia and agenesis; ureteral, urethral, and bladder anomalies; horseshoe and fused pelvic kidney	Heterogeneous, maternal diabetes in some patients	
Cerebro–renal–digital syndromes	Digital and limb anomalies, brain malformations, other anomalies (Table 62-6)	Renal dysplasia, ectopy, and agenesis, ureteral anomalies, fused kidneys	Heterogeneous	
CHARGE syndrome	Coloboma, heart defect, choanal atresia, mental retardation, genital hypoplasia, ear anomalies, deafness	Cystic renal dysplasia, renal agenesis, ureteral anomalies, fused or ectopic kidneys	AD (214800)	<i>CHD7</i>
Chromosome abnormalities	See Table 62-2			
Cloacal exstrophy	Persistent cloaca, exstrophy of the cloaca, failure of fusion of genital tubercles, omphalocele, vertebral defects, spina bifida cystica, abnormal internal and external genitalia	Duplication of urethra, urethral and ureteral anomalies, exstrophy of bladder, renal dysplasia, agenesis and ectopy	Heterogeneous	
DK-phocomelia	Phocomelia, encephalocele, absent corpus callosum, thrombocytopenia	Renal agenesis, fused/ectopic kidney, ureter anomalies	AR (223340)	<i>SALL4</i>
Duane–radial ray syndrome	Radial defects, coloboma, duane anomaly	Renal malrotation/ectopy, partial horseshoe kidney	AD (607323)	
Dysgnathia complex, (Agnathia holoprosencephaly)	Agnathia, synotia, microstomia, holoprosencephaly, cleft lip/palate	Renal agenesis, fusion, or hypoplasia	AD (202650)	
Early amnion rupture (ADAM, amniotic bands)	Digital and limb amputations, ring constrictions, facial clefts, body wall deficiency, brain and other anomalies	Renal dysplasia, agenesis, and ectopy; ureter anomalies, fused/ectopic kidneys, horseshoe kidneys	Sporadic	
Faciocardiorenal syndrome (Eastman–Bixler)	Severe mental retardation, characteristic facies, heart defect	Horseshoe kidneys, hydroureter	AR (227280)	

**TABLE 62-13 Disorders Associated with Horseshoe Kidneys, Renal Ectopy, and Fusion—cont'd**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Fanconi pancytopenia	Anemia, pancytopenia, hyperpigmentation, radial aplasia/hypoplasia, microcephaly, short stature, variable microphthalmia, other anomalies, chromosome breakage	Renal dysplasia, absent kidney (39%), duplication of pelvis and/or ureter, ectopic or horseshoe kidney, hydronephrosis, renal cysts	AR (227650)	<i>FANC</i> (A, C–G, I, J, L–P)
Hand–foot–uterus	Hypoplasia of thumbs and great toes, duplication of female internal genitalia, chordee and hypospadias in males	Ectopic ureteral orifices, hydronephrosis, epididymal cysts, ectopic/fused kidneys, intravaginal urethra	AD (140000)	<i>HOXA13</i>
Hemifacialmicrosomia (oculoauriculovertebral spectrum, Goldenhar)	Facial asymmetry, epibulbar dermoid, coloboma, anotia, preauricular tags, deafness, vertebral anomalies, heart anomalies, variable brain malformations	Renal dysplasia, agenesis, ectopy; hydroureter; abnormal blood supply to kidney; hydronephrosis	Heterogeneous AD (164210)	
Limb–body wall complex	Lateral body wall deficiency, limb reduction anomalies, neural tube defects, severe scoliosis, amniotic entanglements, heart and other anomalies	Renal agenesis or dysplasia, bladder extrophy, fused/ectopic kidneys, ureter anomalies	Sporadic	
McKusick–Kaufman	Hydrometrocolpos, transverse vaginal membrane, vaginal septum, postaxial polydactyly, cardiac anomalies, hypospadias	Hydroureter, ureteral duplication, urogenital sinus, ectopic/fused kidneys ectopic urethra, horseshoe kidneys	AR (236700)	<i>BBS6</i>
MURCS association	Müllerian duct aplasia, renal aplasia, cervicothoracic somite (vertebral) defects, vaginal absence, hypoplastic uterus, short stature	Renal agenesis or dysplasia, ectopia, ureteral anomalies	Sporadic (601076)	
Neural tube defect spectrum	Meningomyelocele, anencephaly, encephalocele, vertebral anomalies, midline anomalies	Renal agenesis, hypoplasia, dysplasia, and fusion; ureteral anomalies	Heterogeneous, commonly multifactorial	
Orocraniodigital syndrome (Juberg–Hayward)	Cleft lip–palate microcephaly, hypoplastic thumbs, elbow deformities	Horseshoe kidneys	?AR (216100)	
Radial–renal syndrome	Hand and limb anomalies, heart anomalies, tracheo-esophageal fistula, split hand/foot	Ureteric reflux, crossed, renal ectopia	AD (179280)	
Roberts (SC phocomelia)	Tetraphocomelia, cleft lip/palate, severe psychomotor retardation, neonatal lethal; chromosomes with premature centromere separation	Renal dysplasia and agenesis, hydronephrosis, horseshoe kidney	AR (268300)	<i>ESCO2</i>
Rubinstein–Taybi	Broad thumbs and toes, distinctive facial features, mental retardation, microcephaly, cryptorchidism, small phallus	Renal dysplasia, absent or extra kidneys, double renal pelvis, renal calculi, posterior urethral valves, abnormal bladder shape, fused/ectopic kidneys	AD (180849)	<i>CREBBP</i>

**TABLE 62-13 Disorders Associated with Horseshoe Kidneys, Renal Ectopy, and Fusion—cont'd**

Disorder	Major Features	Renal Anomaly	Etiology	Genes
Sacral defect with anterior meningocele (sirenomelia)	Single lower limb, sacral agenesis, anal atresia, uterine/vaginal anomalies, cardiac anomalies	Urethral atresia, ectopic urethra, posterior urethral valves, renal agenesis, cystic dysplasia, ureteral and bladder anomalies	AD (600145)	<i>VANGL1</i>
Smith–Lemli–Opitz	Microcephaly, postaxial polydactyly, ambiguous genitalia, facial dysmorphism, 2–3 toe syndactyly, other anomalies	Unilateral renal agenesis, renal dysplasia and fusion	AR (270400)	<i>DHCR7</i>
Twin reversed arterial perfusion (TRAP sequence)	Co-twin with incomplete development of all organs, limbs and body form; upper body more severely affected than lower body	Renal agenesis, hypoplasia, and cystic dysplasia; anomalies of renal fusion/ectopy, horseshoe kidneys; anomalies of ureter, bladder, and urethra	Sporadic, in MZ twins and triplets	

AD, autosomal dominant; AR, autosomal recessive; MZ, monozygotic.

anomaly. Treatment of hydronephrosis and vesicoureteral reflux medically or surgically, when indicated, can greatly reduce associated clinical symptomatology and renal damage. Long-term outcome and mortality are largely determined by the severity of associated anomalies and the presence of disorders of multiple congenital anomalies.

Compared with the general population the risk for renal tumors is increased. Wilms tumor is most frequently reported; others reported include adenocarcinoma, teratomas, and transitional cell tumors (18,89).

## 62.6 ERRORS RESULTING IN OBSTRUCTION

Cystic changes in the kidney can result from obstruction or dysfunction of urinary outflow. Obstruction during embryogenesis and the early fetal period can result in kidney changes that can be difficult to distinguish from renal dysplasia. Obstruction during the late fetal period, infancy, and childhood results in a more characteristic appearance of the “obstructive kidney” with caliectasis and parenchymal scarring. Spina bifida is a common cause of ureteral and bladder dysfunction leading to obstructive changes of the urinary tract. Renal cystic changes caused by obstruction of urinary outflow occurring during the embryonic and fetal period are known as Potter type IV or peripheral cortical cystic dysplasia.

### 62.6.1 Clinical Features

The clinical presentation and course are dependent on the degree of renal parenchymal loss and the underlying etiology of the renal obstruction. The most common anomalies resulting in obstructive kidney(s) are bladder

outlet obstruction (e.g. from PUVs), hydronephrosis due to reflux or vesicoureteral junction obstruction, pelvicaliectasis due to ureteropelvic junction obstruction, ureteral duplication, ureteral strictures, and ureterocele.

Hydronephrosis can result from abnormal innervation of the ureters and bladder (e.g. myelomeningocele), as well as delay in maturation of ureteral muscle function and autonomic muscle weakness (e.g. mitochondrial myopathy). Other renal malformations, such as horseshoe kidney, which are associated with ureteral anomalies, can result in a mixed appearance of renal dysplasia from an error in embryogenesis and secondary changes in the kidney due to obstruction and urinary reflux.

Clinical symptoms are typical of those caused by obstruction, such as urinary tract infections, hematuria, hypertension, oliguria, and, prenatally, oligohydramnios (i.e. Potter) sequence. Other structural anomalies, such as meningo-myelocele, resulting in obstruction, are usually evident on examination. Segmental hypoplasia or Ask-Upmark kidney is characterized by one or more atrophic lobes, which appear as depressions or grooves on the capsular surface of the kidney. The majority of patients with Ask-Upmark kidney will have vesicoureteral and intrarenal reflux, presenting with hypertension or urinary tract infection.

### 62.6.2 Prenatal Diagnosis

Hydronephrosis, pelvicaliectasis, and obstructive cystic changes of the kidneys frequently present during the fetal period. However, fetuses and infants with high-grade vesicoureteral reflux might have normal renal ultrasounds. Dilatation of the ureters is readily detectable by fetal sonogram. Compared with the overall maternal age-related risk, the risk for fetal chromosomal abnormalities is three

times higher when there is an isolated hydronephrosis, and 30 times higher when there are associated malformations of other organ systems (106) (Table 62-10). For families at risk for fetuses affected with autosomal dominant hydronephrosis, serial ultrasound scans are recommended, since obstruction increases as fetal renal function improves. Fetal ultrasound is very reliable for prenatal diagnosis of obstruction of the urinary tract. In utero treatment of eligible fetuses is offered only in a few centers and remains experimental. Fetuses with evidence of significant hydronephrosis and some degree of oligohydramnios with potentially reversible renal damage, who do not have underlying disorders with a poor prognosis, are the best candidates for in utero drainage with catheter placement or fistulae formation between the dilated ureter and the amniotic sac.

### 62.6.3 Genetics

Autosomal dominant inheritance of unilateral hydronephrosis has been reported in families. Simpson and German (107) described seven families with multiple cases of urinary tract anomalies, mostly with obstructive uropathy, and reviewed cases in sibs, twins, and other relatives. Familial occurrence has also been reported for bilateral megalo ureters with hydronephrosis and for hydronephrosis due to ureteropelvic junction stricture, aberrant vessels, duplication of the ureter, unilateral hydronephrosis, and ureterocele. Ureteral anomalies and secondary obstruction are common and do not usually have enough specificity to be helpful in making a diagnosis of a specific disorder. Disorders commonly associated with ureteral anomalies and secondary obstructive renal cystic disease are discussed in previous sections.

Izquierdo and colleagues (108) found linkage to human leukocyte antigen (HLA) by analyzing five families with hereditary pelviureteric junction obstruction. Maximal lod scores were 3.090 at a recombination fraction of 0.11 with full penetrance, and 2.486 at a recombination fraction of 0.1 with 90% penetrance. Use of the HOMOG program suggested genetic heterogeneity with one locus on 6p in four of the families and a different locus in one family. After exclusion of the unlinked family, two-point analysis gave a maximal lod score of 3.9 at a recombination fraction of 0.05 with full penetrance, and 4.2 at a recombination fraction of 0.0 with 90% penetrance. Further evidence for the 6p locus being important in hydronephrosis is the report by Fryns and colleagues (109) of a de novo chromosome translocation t(6;19)(p23.1;q13.4) in a fetus with oligohydramnios and bilateral massive hydronephrosis and multicystic renal dysplasia secondary to pelviureteric junction obstruction.

### 62.6.4 Primary Vesicoureteral Reflux and Reflux Nephropathy

Vesicoureteral reflux has been comprehensively reviewed by Williams et al. (110). Primary vesicoureteral reflux refers

to the retrograde flow of urine from the urinary bladder toward the kidney. It is estimated to occur in about 1% of children, and in the majority of cases, it clears over time. Vesicoureteral reflux is usually discovered during imaging investigations of children with urinary tract infections. A small proportion of these patients progress to end-stage renal disease. This progressive condition, known as reflux nephropathy, consists of calyceal clubbing or deformity with overlying corticomedullary scarring. Vesicoureteral reflux in utero has been associated with renal hypoplasia and dysplasia; lesions seen in the end-stage kidney include chronic tubulointestinal nephritis and focal glomerulosclerosis.

**62.6.4.1 Pathogenesis of Primary Vesicoureteral Reflux.** The anatomic lesion is due to incompetence of the vesicoureteral junction. Normally the retrograde flow of urine from the bladder is impeded by the length of a submucosal ureteric “tunnel,” the size of the ureteric opening and the crossing of the bladder wall trigone muscles during voiding at the point at which the ureter inserts into the urinary bladder. The severity of vesicoureteral reflux is graded on a scale of I to V on voiding cystourethrography with a separate, more worrisome variant of intrarenal reflux where urine flows back into the renal parenchyma through the collecting ducts.

Developmentally primary vesicoureteral reflux (VUR) arises from disruption in complex signaling pathways and cellular differentiation that may also be influenced by environmental factors in utero. Abnormal ureteric budding and disturbed interactions between the ureteric bud and metanephric mesenchyme has been implicated from animal studies with knockout mice. Lu et al. (111) found evidence for defective SLIT-ROBO signaling pathways in the pathogenesis of a subset of human VUR. ROBO2 plays a key role in the formation of the ureteric bud; its inactivation in mice leads to supernumerary ureteric buds, lack of ureter remodeling, and improper insertion of the ureter into the bladder. Bertoli-Avella et al. (112) found a relatively high frequency of ROBO2 variants in familial cases of primary VUR in their cohort of patients. Animal models have suggested that RET-mediated signaling pathways are required for the final formation of the vesicoureteral junction. Yang et al. (38) found that a RET GLY691Ser mutation is associated with primary vesicoureteral reflux in a French-Canadian population from Quebec.

**62.6.4.2 Genetics.** Autosomal dominant inheritance with variable expression or multifactorial inheritance has been implicated for primary vesicoureteral reflux and reflux nephropathy (110). In a study of first-degree relatives (51 parents and 43 siblings) of 26 affected children, an overall risk of 17% was found, with 23% of siblings and 12% of parents having evidence of reflux nephropathy or vesicoureteral reflux. The risk for other family members being affected appears to be higher if the proband presents with renal failure. Kaefer and colleagues (113) found 100% concordance among very young monozygotic twins and 50% concordance among dizygotic twins. Feather and

colleagues (114) found that VUR mapped to a locus on chromosome 1 in several European families whose pedigree was consistent with dominant inheritance. As adults, 45% of these affected individuals will have vesicoureteral reflux or reflux nephropathy or both, and in 15%, renal failure will develop. Many clinicians recommend radionuclide voiding cystography as a screening investigation of all first-degree relatives. Weng et al. (115) performed a genome-wide linkage scan in 12 large families with primary VUR and found a linkage signal on chromosome 12p11-q13 suggesting that recessive inheritance may be operative in certain cases.

The HLA haplotypes A2-B8 and A9-B12 are more frequent in patients with reflux nephropathy than in patients with other end-stage renal diseases. Kuroda et al. (116) found that individuals with the transforming growth factor-beta1-509CC and 869TT genotype may have an increased susceptibility to vesicoureteral reflux.

**62.6.4.3 Diagnosis and Differential Diagnosis.** Diagnostic investigations include a voiding cystourethrogram to demonstrate reflux, CT urography or nuclear scan for detection of renal scarring, and CT urography or renal ultrasonography for detection of structural anomalies. An international classification system is used for grading of vesicoureteral reflux (110).

**62.6.4.4 Management.** The clinical course is dependent on the degree of renal parenchymal loss and the underlying etiology for the renal obstruction. Patient management is directed toward reducing ongoing damage to the kidneys from reflux nephropathy, and preventing recurrent infection through the use of prophylactic antibiotics (117, 119). Children with high grades of vesicoureteral reflux may be treated with surgical interventions such as ureteral reimplantation. The long-term use of ACE inhibitors does not seem to reduce the progressive loss of renal function (118).

### 63.1 INTRODUCTION

Cystic diseases of the kidney are some of the most significant monogenic causes of renal morbidity and mortality in both pediatric and adult populations. There have been considerable advances in the past decade in identifying and characterizing the genes responsible for these disorders. The genetic aspects, molecular pathogenesis, clinical features, and management of these disorders will be highlighted in this chapter. Although cystic renal disease can be acquired, the primary aim of this chapter will be to focus on those forms that are inherited.

### 63.2 AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE (MIM 173900)

#### 63.2.1 Clinical Features and Natural History

The dominant form of polycystic kidney disease (PKD), once called “adult polycystic kidney disease,” is one of the most significant monogenic causes of morbidity and mortality in the adult population. It is estimated to affect 12.5 million people worldwide with a prevalence of 1/800 live births and accounts for 5–10% of all cases of adult end-stage renal disease (ESRD) (1). Two genes, *PKD1* and *PKD2*, have been identified to cause autosomal dominant polycystic kidney disease (ADPKD). Patients with a *PKD1* mutation have earlier onset of disease and more complications, reach ESRD faster, and die sooner than patients with *PKD2* mutations.

ADPKD is usually asymptomatic until adulthood, typically beginning in the fourth to fifth decade of life. Hematuria, renal colic, recurrent urinary tract infection (UTI),

lower back discomfort, and hypertension are common presenting symptoms. Progression to ESRD is an invariant feature of the disease. Factors that predict earlier onset of ESRD include hypertension, proteinuria, and mutations in *PKD1*. Women with *PKD2* mutations preserve renal function longer than men with the same mutations, but no gender difference is observed with *PKD1* mutations. Median age of onset of ESRD or death is 53 years in *PKD1* patients and 69 years in *PKD2* patients (2).

Although ADPKD is a completely penetrant disorder, a significant degree of clinical variability exists. Approximately 50% of patients develop hypertension with a mean age of onset of 31 years, long before the development of ESRD and sometimes before the discovery of renal cysts (1). Cyst enlargement and compression of normal parenchyma is hypothesized to decrease intrarenal perfusion and activate the renin–angiotensin–aldosterone (RAA) system, leading to hypertension (3). However, this theory does not adequately explain why the age- and gender-adjusted prevalence of hypertension is four times greater in those with *PKD1* compared to *PKD2* mutations. About 25–30% of patients develop cyst infection, and 18–25% of patients develop gross hematuria from cyst hemorrhage. Nephrolithiasis, seen in 10% of all patients, occurs with equal frequency in *PKD1* and *PKD2*, and is due mostly to either oxalate or urate stones (2). Expanding cysts compressing the collecting system producing urinary stasis, along with low urine pH and hypocitraturia, contribute to stone formation.

Hepatic cysts present approximately 10 years after the development of renal cysts. The number and size of these cysts increases with age. Approximately 80% of ADPKD patients have hepatic cysts by age 50 (4,5). Female gender and increased gravidity also correlate with increased

burden of liver involvement. Polycystic liver disease is rare in children and is typically asymptomatic. Symptoms are being seen more commonly as the life span of ADPKD patients has lengthened with dialysis and transplantation (6). The primary complication of polycystic liver disease is severe hepatomegaly with abdominal discomfort and shortness of breath; hepatic function is preserved. Cyst infection, hemorrhage, and post-traumatic rupture occur much less often. Portal hypertension with ascites, variceal bleeding, and encephalopathy are very rare but are perhaps the most significant hepatic sequela of ADPKD (7).

Cardiac disease, specifically mitral valve prolapse (MVP), hemodynamically significant mitral regurgitation (MR), or aortic insufficiency (AI), is also seen in patients with ADPKD. The estimated prevalence of MVP is 25–30%, MR 13%, and AI 8% (8–10). Valvular changes are due to myxomatous degeneration and loss of collagen. Patients with hypertension also develop compensatory left ventricular hypertrophy. Dilatation of the aortic root and thoracic aortic dissection have also been reported. Although abdominal aortic aneurysms and dissection were thought to occur with increased frequency in ADPKD patients, subsequent studies have shown that this is not the case (11).

Intracranial aneurysms, typically small saccular aneurysms of the circle of Willis, are found in approximately 10% of all ADPKD patients and are less common in those younger than 30 years (12,13). PKD1 and PKD2 patients are equally at risk (14). Aneurysms are found in 22–25% of those with a family history of aneurysms and ADPKD, and 6% of those without a family history (15,16). Most aneurysms are small, with 90% less than 10mm in diameter and 70% less than 6mm in diameter (17). Over 95% of aneurysms identified in asymptomatic screening are less than 6mm in diameter (15–19). Aneurysm surveillance studies indicate that aneurysms smaller than 10mm have a low rupture risk of 0.05% per year, but since the studies were done on the general population, it is uncertain whether this low risk can be applied to ADPKD patients alone (20).

Aneurysmal rupture results in subarachnoid hemorrhage (SAH), perhaps the most sudden and devastating complication of ADPKD. Symptoms of rupture are no different from those in non-ADPKD patients and include sudden-onset severe headache, acute focal neurologic deficit, altered mental status, nausea, vomiting, or photophobia. The estimated immediate mortality of such an event is 10%, with 38% long-term, permanent morbidity in survivors (21). The mean age of rupture is 40 years, with 65–75% of all ruptures occurring prior to age 50 (13). About 10% of aneurysm rupture occurs in ADPKD patients younger than 20 years (22). Recognition of symptoms of SAH and emergent neurosurgical intervention are crucial for survival and reduction of long-term morbidity.

Colonic diverticular disease has been reported to occur with increased frequency in ADPKD patients with ESRD awaiting transplant, but not in patients without ESRD (23,24). Diverticulitis, if not recognized and

treated promptly, can lead to colonic perforation. Ventral and inguinal hernias have also been documented in ADPKD patients with ESRD (25–27).

In males, cysts can be found in the seminal vesicles, epididymis and prostate. Sperm abnormalities and defective motility can be also seen but rarely cause male infertility (28). Cysts of the pancreas are rare and usually asymptomatic. However, patients may develop recurrent pancreatitis and intraductal papillary mucinous tumor or carcinoma. Arachnoid cysts may occur and present with headache, diplopia, hearing loss and ataxia due to cerebrospinal fluid leak (29).

### 63.2.2 Gene Mapping, Structure, Function, and Genotype–Phenotype Correlations

Early studies demonstrated linkage between the *PKD* locus and the  $\alpha$ -globin locus on chromosome 16p. Subsequent linkage studies refined the locus to a 750 kilobase (kb) segment at 16p13 (30,31). The presence of several *PKD* pseudogenes made direct positional cloning difficult, but in 1995, sequencing of the *PKD* cDNA showed a 14,148 bp transcript with 46 exons spanning 52kb of genomic DNA (32). The *PKD* protein, initially termed polycystin and renamed polycystin-1 after the discovery of a second *PKD* locus, is a plasma membrane protein 4304 amino acids long weighing 463 kilodaltons (kDa) (Figure 63-1). The N-terminal extracellular region is composed of an aggregation of multiple domains involved in protein–protein and protein–carbohydrate interactions, while the C-terminal intracellular region ends in a series of protein–protein interaction motifs called coiled-coil regions. In addition to the extracellular and intracellular signaling regions, polycystin-1 contains a sea urchin receptor for egg jelly (suREJ) domain. This domain offers some insight into the function of the protein. The sea urchin homolog is involved in the activation of the sperm's acrosome reaction (33). Contact of

**FIGURE 63-1** Torress, V. E.; Harris, P. C. Autosomal Dominant Polycystic Kidney Disease: The Last 3 Years. *Nature* 2009, 76 (2).

the sperm with the egg's zona pellucida results in calcium ion influx triggered by the suREJ protein, leading to release of proteolytic enzymes and polymerization of globular actin.

Several years after linkage of PKD to the  $\alpha$ -globin locus, two families with PKD were described who did not link to chromosome 16p (34,35). Clinical characteristics of these families were indistinguishable from those linking to *PKD1*. Identification and study of more PKD families unlinked to the first PKD locus resulted in the discovery of a 680kb segment on chromosome 4q21, from which the *PKD2* gene, encoding the polycystin-2 protein, was cloned (36). The *PKD2* gene consists of 15 exons spanning 68kb and encodes a 5.4kb mRNA. The polycystin-2 translated product, a 110kDa protein, contains 968 amino acids and 6 transmembrane domains (Figure 63-1). Polycystin-2 belongs to a subfamily of transient receptor potential channels and functions as a calcium channel. The C-terminal intracellular region shares homology with the C-terminal region of *PKD1*, and co-immunoprecipitation studies indicate that *PKD1* and *PKD2* interact with one another via their C-terminal coiled-coil regions (37,38).

Polycystin-1 and polycystin-2 are ubiquitously expressed, at higher levels during embryonic development, then at lower levels during postnatal and adult life (39–41). mRNA expression is observed in the brain, cardiac and skeletal muscles, smooth muscle of blood vessels, vascular endothelium, breast, lung, liver, pancreas, kidney, and reproductive organs (42,43). Within the fetal kidney, the two proteins are expressed in maturing renal tubular epithelium and at lower levels at the distal ureteric buds. Both proteins are required for normal embryonic development; *PKD1* knockout mice die at birth because of pulmonary hypoplasia from massive cystic enlargement of the kidneys and pancreas while the *PKD2* knockout dies in the late embryonic period with abnormalities in cardiac atrioventricular septation and cysts in the kidneys and pancreas (44,45). Postnatally, the proteins are seen in the distal convoluted tubular and collecting duct epithelia.

Mutations in *PKD1* account for 85% of cases of ADPKD, while most of the remaining mutations are found in *PKD2* (46). To date, 864 germline *PKD1* mutations have been reported (47), most of which result in protein truncation. Of the 436 mutations that are classified as pathogenic, 134 (31%) are frameshift mutations, 110 (25%) nonsense mutations, 95 (22%) substitutions, 45 (10%) splice site mutations, and 36 (8%) insertions and deletions. The high mutation rate in the *PKD1* gene is thought to be related to the large polypyrimidine tract in intron 21, the longest such tract known in the human genome (48). The high cytosine and thymine content allows for triple-helix formation, which can result in mutagenesis.

Like mutations in *PKD1*, a large majority of germline *PKD2* mutations result in a truncated protein

product. A total of 139 mutations have been described, of which 115 have been classified as pathogenic (47). Of these, 50 (43%) are frameshift mutations, 30 (26%) nonsense mutations, 17 (15%) splice site mutations, 11 (10%) missense mutations, and 6 (5%) insertions or deletions. While the mutations are located throughout the *PKD2* gene, a slight clustering of mutations is seen in exons 4, 5, and 6, which make up 24.2% of the cDNA sequence but account for 38.6% of germline mutations. There are several unrelated families (by ethnicity and haplotype analysis) with identical mutations, indicating a few mutation-prone “hot spots,” but most *PKD2* germline mutations are unique to the affected family.

A very small percentage (<1%) of ADPKD families do not demonstrate linkage to either *PKD1* or *PKD2* (49). The existence of a third ADPKD gene has been suggested, but there has been no definitive evidence to support this hypothesis. Common confounders, such as genotyping errors, nonpaternity, and misdiagnosis (including phenocopies and nonpenetrance) may explain this apparent disparity (49).

Although all cells in an ADPKD kidney inherit the same germinal mutation, histopathologic studies indicate that only 1–5% of all nephrons have cysts (50). Experience gained from *Rb* mutations and hereditary retinoblastoma led to the hypothesis that a “second hit,” or somatic inactivation of the normal PKD gene, is necessary to trigger cystogenesis in both the kidney and the liver. The second hit hypothesis was confirmed in both *PKD1* and *PKD2* patients. Clonal loss of heterozygosity, specifically, loss of the normal *PKD1* haplotype, was demonstrated in cysts isolated from *PKD1* kidneys (51,52), and the same was demonstrated for *PKD2* kidney and liver (53). Truncating and missense mutations from the normal *PKD1* haplotype were discovered (54). Cysts from *PKD2* kidneys and livers were also found to have truncating mutations in the inherited wild-type *PKD2* gene (53,55). These studies indicate that, while inherited in a dominant fashion, ADPKD is recessive at the cellular level. In addition, a trans-heterozygous state can arise when compound heterozygous mutations occur in both *PKD1* and *PKD2* (54,56).

With regard to genotype–phenotype correlations, it is well known that mutations in *PKD1* are associated with more severe disease than those in *PKD2*. Individuals with *PKD1* mutations are diagnosed at an earlier age, have a higher incidence of hypertension and hematuria, and progress to ESRD on average 20 years earlier (2,57). *PKD1* kidneys are significantly larger than age-matched *PKD2* kidneys because of a greater number of cysts rather than the rate of cystic expansion (58,59). This finding is consistent with the two-hit model of cystogenesis as *PKD1* is more prone to mutation.

Mutations of any type at the 5' end of *PKD1* are correlated with decreased renal survival, earlier onset of ESRD, and increased risk of intracranial aneurysms

compared to mutations at the 3' end of the gene. There appears to be no significant difference in the severity of disease between families with truncating, in-frame, or missense deletions (14,60). With *PKD2*, splice site mutations appear to produce milder renal symptoms compared with other types of mutations (61). Excepting this association, no other genotype–phenotype correlations have been determined from mutational analysis (62,63). There is, however, a gender effect observed with *PKD2* disease, with females having milder renal involvement than males (61).

In addition to the phenotypic variation observed in families with different mutations, individuals within a family can manifest with differing degrees of clinical severity (63). Genetic modifiers have been purported to play a role in this intrafamilial variability, and their effect has been estimated to be between 18 and 59% in those with *PKD1* mutations (64). Thus far, association studies of the angiotensin-1-converting enzyme (*ACE*) gene and the endothelial nitric oxide synthase (*ENOS*) gene have shown equivocal results (65–68). One clear example of genetic background affecting phenotype expression is the contiguous gene deletion syndrome involving the tuberlin (*TSC2*) and *PKD1* genes, both located on chromosome 16p13.3 (Figure 63-2) (69). Affected individuals suffer from tuberous sclerosis and have severe polycystic kidney and liver disease typically arising in infancy to early childhood with rapid progression to ESRD. In the past, tuberlin was thought to function in localizing polycystin-1 to the plasma membrane (70). More recent studies have shown that the cytoplasmic tail of polycystin-1 directly interacts with tuberlin in the mammalian target of rapamycin (mTOR) pathway, and inhibition of this pathway reverses renal cystogenesis (71).

Nongenetic factors also contribute to phenotypic variation. Hormonal effects have been described, including the predominance of cystic liver disease in females due to the effects of estrogen (72). Smoking and other

promutagenic factors may confer higher risk by increasing the chance for somatic mutations, thereby providing the “second hit” (73).

### 63.2.3 Laboratory, Imaging, and Histopathologic Findings

Serum electrolyte studies are normal unless there is ESRD. Urinalysis reveals microscopic or gross hematuria in about 40–45%, especially if there is cyst hemorrhage (74). Dipstick proteinuria is present in 20% of patients and microalbuminuria in about 35% (75). Liver transaminases, alkaline phosphatase, and markers of hepatic synthetic function such as prothrombin time and partial thromboplastin time are usually normal even with severe cystic disease.  $\gamma$ -Glutamyltransferase levels correlate with hepatic cyst burden (7).

Abdominal ultrasound is the modality of choice for diagnosis of ADPKD. The Ravine criteria are highly specific (near 100%), but sensitivity is age dependent, i.e. the longer an individual remains negative, the lower the likelihood of disease (Table 63-1). Sensitivity is lower in *PKD2* patients less than 30 years of age (67%) because of later age of onset; therefore, an individual at risk for *PKD2* must undergo either molecular diagnostic testing or ultrasound surveillance continued beyond the age of 30 (76). Enlarged kidneys with multiple anechoic cysts

TABLE 63-1

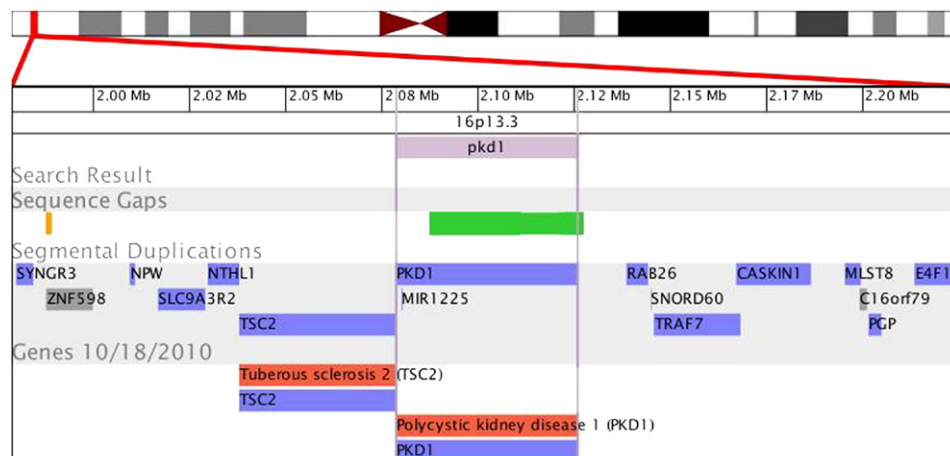

FIGURE 63-2 Figure of the genes *PKD1* *TSC2*. Signature genomic genome browser.

of varying sizes throughout the cortex distorting normal pelvicalyceal architecture are seen. Cyst hemorrhage or infection may be visualized as echogenic debris within the cyst. Hepatic, pancreatic, and splenic cysts can be visualized with ultrasound as well. Computed tomography (CT) with intravenous contrast or magnetic resonance imaging (MRI) can be used for diagnosis of ADPKD when higher resolution imaging is required.

Renal biopsy of patients with ADPKD is not recommended because of risk of bleeding. Gross renal specimens are enlarged with cysts present over the surface of the kidney. Cut specimens reveal cysts throughout the thickness of the kidney, filled with straw-colored, serosanguinous, or brown fluid. Infected cysts are filled with purulent material. Microscopically, interstitial fibrosis and intact nephrons can be seen in the parenchyma between cysts. Cysts are lined with renal epithelium originating primarily from the proximal convoluted tubule and collecting duct. Hepatic cysts are lined with biliary duct epithelium.

### 63.2.4 Molecular and Prenatal Diagnosis

As mentioned earlier, abdominal ultrasound is the diagnostic test of choice, especially for individuals at risk for PKD1. CT or MRI may be used as an adjunct if ultrasound is equivocal and higher resolution studies are required. Molecular diagnostic testing is commercially available for both *PKD1* and *PKD2*. Sequence analysis has a mutation detection rate of approximately 90% for *PKD1* (46). An additional 4% of patients may have gross rearrangements, which are detectable using multiplex ligation-dependent probe amplification (77). For *PKD2*, over 90% of mutations are identified with direct sequence analysis. There are limitations to molecular testing, however. Most *PKD1* and *PKD2* mutations are “private mutations,” with very few recurrent mutations. Consequently, sequencing results must be interpreted with caution, as some sequence variations may represent polymorphisms that are not pathogenic. In fact, each individual is known to carry more than 10 polymorphic variants in the *PKD1* gene (78). In addition, exon sequencing does not detect mutations in the noncoding regions of the genes.

Prenatal diagnosis can be performed via analysis of cells obtained from chorionic villus sampling or amniocentesis if linkage to a specific haplotype or disease-causing mutation has already been established. However, due to the availability of treatment, lack of cognitive impairment, and adult onset of disease, prenatal diagnosis is usually not performed unless there is a family history of a severely affected infant.

### 63.2.5 Management

Since there is no definitive treatment for the underlying genetic defect of ADPKD, management is limited to surveillance for and control of the disease complications.

However, currently there are a number of novel therapies in clinical trials that could be used in the management of these patients in the future.

**63.2.5.1 Hypertension.** Since hypertension and proteinuria are predictors of earlier onset of ESRD, and the RAA system is the key mechanism underlying hypertension in ADPKD, angiotensin-converting enzyme inhibitors (ACE-i), which target the RAA system, decrease blood pressure, and reduce proteinuria, would seem to be the treatment of choice. There have been epidemiologic and nonrandomized studies suggesting that ACE-i can slow the progression of renal insufficiency and reduce proteinuria (79–81). However, the few randomized, prospective studies on ACE-i have indicated otherwise. The Modification of Diet in Renal Disease (MDRD) Study Group was a randomized, prospective trial that included 200 patients with ADPKD and found that treatment with low-protein diet or ACE-i did not slow the loss of glomerular filtration rate (GFR) (81). The ACEi in Progressive Renal Insufficiency Study included 64 patients with ADPKD and found that treatment with benazepril did not decrease the number of patients who experienced doubling of serum creatinine or required initiation of dialysis (82,83). Finally, no difference in GFR decline was noted in hypertensive ADPKD patients treated with either atenolol (a  $\beta$ -blocker) or enalapril. No significant decrease in microalbuminuria was noted either. Normotensive ADPKD patients treated with enalapril did not have any significant decrease in GFR decline compared to those not treated (84). There are no data to suggest that antihypertensive therapy reduces the risk of intracranial hemorrhage or cardiac disease in ADPKD patients. However, a randomized study that compared standard versus strict control of hypertension (blood pressure less than 135–140/85–90 mmHg versus 120/80 mmHg) found significantly decreased left ventricular mass index, a cardiovascular disease risk factor, in patients with strict control (85). While this study indicates that antihypertensive therapy is probably beneficial in ADPKD, it did not examine cardiac end points such as myocardial infarction, cardiomyopathy, or congestive heart failure. Other therapies include angiotensin receptor blockers (ARBs), which act in a manner similar to that of ACE-i. Since hypertension is an independent factor that increases the morbidity of ESRD patients, therapy with ACE-i and/or ARBs is encouraged.

**63.2.5.2 Dialysis and Renal Transplantation.** At onset of ESRD, renal replacement therapy with dialysis should be initiated or, if living donors are available, patients should be evaluated for preemptive kidney transplantation. Assessment for ventral hernias, which interfere with peritoneal dialysis, should be performed prior to consideration for peritoneal catheter placement. Outcomes of renal transplantation are comparable with all non-diabetic renal transplant patients, with 73% 5-year and 67% 10-year graft survival and 84% 5-year and 73% 10-year patient survival rate (86,87). Malignancy due to

chronic immunosuppression is the most common cause of graft failure and patient death (88). Patients with ADPKD are excellent candidates for transplantation, but living related donor transplantation must be carefully assessed because of the high risk of disease in relatives and late onset of cysts in some of them. Owing to these concerns, potential living related donors should undergo genetic testing or be screened carefully for evidence of ADPKD before proceeding to living donation.

**63.2.5.3 Polycystic Liver Disease.** There are no effective medical therapies for polycystic liver disease, and since most patients have no symptoms, no treatment is recommended. The observation that postmenopausal women with ADPKD taking hormone replacement therapy have higher burden of hepatic cysts prompted a recommendation to avoid estrogen, but there are no studies that indicate that avoidance of estrogen or estrogen receptor blockade is effective (7). Patients with symptomatic liver disease and a few dominant cysts may be candidates for CT-guided aspiration/sclerosis or laparoscopic cyst fenestration, but most symptomatic patients have too many cysts for these techniques to improve symptoms. There is a risk of bleeding, bile leak, ascites, or recurrent symptoms with these techniques, and some patients may require conversion to open laparotomy. Partial liver resection has been attempted in patients with severe symptoms and hepatomegaly with relief of symptoms, but there is a high risk of perioperative morbidity (7). Orthotopic liver transplantation (OLT) or combined liver and kidney transplantation is reserved for those patients who have ESRD and severe refractory liver disease or for patients with symptomatic portal hypertension, Budd–Chiari syndrome, or intrahepatic biliary obstruction. Five-year survival is 69% for OLT alone and 76% for combined OLT and renal transplantation (7).

**63.2.5.4 Abdominal Pain.** Abdominal pain should not be disregarded in ADPKD patients, as nephrolithiasis, renal cyst bleeding, diverticulitis, lower UTI, and cyst (renal or hepatic) infection are common. Nephrolithiasis should be treated with analgesia, bed rest, and hydration. Renal cyst hemorrhage is usually self-limiting and treated in the same manner as nephrolithiasis, but caution must be exercised if pain worsens, as retroperitoneal hemorrhage with severe blood loss and hypovolemia has been reported. Diverticulitis in end-stage ADPKD patients must be recognized promptly and treated with antibiotics and bowel rest. Lower UTI presents in the usual manner with frequency, urgency, and dysuria. Oral antibiotics that cover gram-negative enterobacteriaceae should be administered for the standard duration.

Cyst infections, however, are more difficult to recognize and treat. Renal cyst infections are likely due to ascending infection, as suggested from the observation that 92% of cyst infections occur in females (89). Renal cyst infection classically presents with fever and focal tenderness overlying the affected kidney, hepatic cyst infection with fever and right upper quadrant

tenderness. However, some patients have more subtle clinical signs. Not all patients with renal cyst infection have pyuria or positive urine cultures. Leukocytosis and elevated erythrocyte sedimentation rate aid somewhat in diagnosis, but blood culture has been shown to be the most effective diagnostic test for both renal and hepatic cyst infection (89,90). 18F-fluorodeoxyglucose positron emission tomography has become a promising agent for detection of infected cysts, but can be expensive (91,92). Empiric therapy with an antibiotic that penetrates into the cyst, such as ciprofloxacin, trimethoprim-sulfisoxazole, or vancomycin, should be initiated in patients with suspected cyst infection. Enterobacteriaceae are the usual pathogens. If an organism is identified, the patient should receive an extended course of treatment lasting a minimum of four weeks to ensure adequate cyst penetration; CT-guided drainage may be necessary with cyst infections that do not respond.

**63.2.5.5 Cardiac Disease.** Periodic echocardiography should be performed to assess for valvular disease, left ventricular hypertrophy, and dilatation of the aortic root. Subacute bacterial endocarditis prophylaxis should be given prior to dental and gastrointestinal procedures if there is hemodynamically significant valvular insufficiency. Valve replacement is indicated for severe, symptomatic regurgitation.

Monthly to bimonthly monitoring of the aortic root should be performed if the aortic root reaches 4 cm, and aortic root replacement is indicated if the diameter of the aortic root exceeds 5 cm. This recommendation, however, is based on data from patients with Marfan syndrome. There are no ADPKD patient studies that follow the velocity of aortic root dilatation or assess the risk of aortic dissection in relation to aortic root diameter. It is also not known whether  $\beta$ -blockade in ADPKD patients with aortic root dilatation can successfully slow the rate of dilatation as in Marfan syndrome.

**63.2.5.6 Screening of Intracranial Aneurysm.** Prior to the development of MRI and magnetic resonance arteriography (MRA), routine screening of all ADPKD patients was not recommended because the screening test, intra-arterial angiography, held a significant risk of complications including permanent neurologic deficit (93,94). High-resolution time-of-flight MRA is now the modality of choice for aneurysm screening. While the technique is highly specific and sensitive for aneurysms 5 mm in diameter and above, the sensitivity drops considerably for smaller aneurysms (95). CT angiography has been shown to have better sensitivity, but the requirement of intravenous contrast may render this study unfeasible for patients with chronic renal insufficiency (CRI) or ESRD (96).

While screening relatives of patients with SAH successfully identified small, asymptomatic aneurysms and resulted in more surgical interventions performed, the resultant operative complications, postoperative morbidity, and long-term reduction in function outweighed any benefits gained from preventing SAH (20,97). Caution,

however, must be exercised in extrapolating the data to ADPKD patients, where only theoretical cost-benefit analyses have been performed (98,99).

The current recommendation is to screen only ADPKD patients with a past history of SAH or a family history of SAH or aneurysm, beginning at age 20. Since aneurysm rupture has been observed following renal transplantation, other groups have suggested screening of those planning to undergo major elective surgery. Individuals in “high-risk” professions such as airline pilots have also been identified as candidates for screening (22,100).

Very few individuals (2.4%) without aneurysm identified at initial screening developed an aneurysm in a 10-year longitudinal study (101). Studies of those with an aneurysm found at screening have shown that aneurysmal enlargement or development of new aneurysms occur slowly. In one study of 18 individuals with an aneurysm found at screening, one developed a new aneurysm and one experienced enlargement of the existing aneurysm (19). Both events occurred in the group of 10 patients imaged over an average period of 10 years and previously reported in a separate study (102). None of the patients followed for less than 10 years developed a new aneurysm. In another study, 25% (5 of 20) of individuals with previously identified aneurysms developed new aneurysms over an average 15-year follow-up period. Four of those five were initially discovered to have intracranial aneurysm when they experienced an intercranial bleed; none had recurrent intercranial bleeding (103). These findings suggest that those who have experienced SAH have a high incidence of developing new aneurysms, an observation born out by other studies that have also shown that they are at higher risk of aneurysm rupture (104). Although there are no specific recommendations for imaging intervals, these data indicate that those who screened negative should have the longest interval for reimaging (5–10 years), those with asymptomatic aneurysms an intermediate interval (3–5 years), and those with prior history of SAH the shortest (1–3 years). Clipping of an aneurysm or intra-arterial coiling should be performed in patients with aneurysms that are symptomatic or larger than 10 mm.

**63.2.5.7 Novel Therapies.** Better understanding of the pathophysiology and the availability of animal models have led to the identification of several promising drugs that are in clinical trials. Inhibition of cAMP has been shown to reduce the growth of cysts. Vasopressin V2 receptor antagonists (VPV2R) reduce renal levels of cAMP and therefore inhibit cyst development in animal models. Tolvaptan, a VPV2R, has completed phase II clinical trials, and a phase III trial is ongoing (NCT00428948). Somatostatin inhibits cAMP in the kidney and liver. Clinical trials with octreotide and lanreotide for PKD and cystic liver disease are ongoing (NCT00309283, NCT00426153, NCT00565097). Animal studies have also shown that the mTOR is involved in the coordination of cell growth and proliferation, the

uncontrolled activation of which has been implicated in the pathogenesis of ADPKD. In animal models, the mTOR inhibitors, sirolimus and/or everolimus, significantly retard cyst expansion and protect renal function. Prospective, randomized clinical trials with these drugs are in progress (NCT00346918, NCT00286156, NCT00414440) (6).

### 63.3 AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE (MIM 263200)

#### 63.3.1 Clinical Features and Natural History

Autosomal recessive polycystic kidney disease (ARPKD) affects approximately 1:10,000–40,000 live births, without ethnic variation (105–108). The true incidence may be higher, as severely affected infants may die as newborns without a diagnosis, and patients with mild disease may not be diagnosed until later in life (109). The carrier frequency of the causative gene is reported to be 1:70 (110). ARPKD was considered to be a fatal condition of infancy, but more recent case series indicate a wider range of phenotypic severity and age of onset. Approximately 50% of cases are identified prenatally by ultrasound or at birth (108). Oligohydramnios, nephromegaly, echogenic kidney parenchyma, small cysts below 2 cm in diameter, and loss of corticomedullary differentiation are highly suggestive of ARPKD (111). However, ultrasound is unreliable for prenatal diagnosis, as not all affected fetuses, especially those with milder involvement, display these signs (112).

As a result of oligohydramnios, affected infants have Potter facies (hypertelorism; prominent infraorbital creases; flattened nasal bridge and tip; low-set, flattened, fleshy pinnae; and micrognathia), talipes equinovarus due to extrinsic compression, and respiratory insufficiency with subsequent air leaks (pneumothorax or pneumomediastinum) due to pulmonary hypoplasia. Neonatal mortality is estimated at 20–50% depending on the case series and is due to critical respiratory insufficiency, not from renal or liver disease (113–116).

Infants who survive the first month of life have a good chance of surviving the first year of life, with studies showing 78–87% 1-year and 50–87% 5-year survival rates (1,107,117). Ten-year survival is estimated at 87%, and 15-year survival ranges from 67 to 79% (113,114). Survivors face significant morbidities, and those who require neonatal mechanical ventilation have earlier onset of problems. About 20–25% of patients have growth retardation (108), 65% have systemic hypertension with median onset at 7 and 70 days of life in ventilated and nonventilated patients, respectively, and 40% have chronic renal failure with median onset at 1 day and 1 year of life in ventilated and nonventilated patients, respectively (107). This discrepancy is most likely the

effect of children who, because of milder symptomatology and lack of respiratory insufficiency, were not diagnosed with ARPKD until later in infancy or childhood. ESRD, found in 10–30% of patients, typically presents in the first decade of life (107,112,116). Unlike ADPKD, renal size does not increase with progression of renal insufficiency.

Clinical signs and imaging findings in children who present after the neonatal period are not as reliable. The more consistent feature in these children tends to be hepatic disease. Liver disease involves abnormal intrahepatic biliary duct hyperproliferation and dilatation, with subsequent hepatocellular damage, inflammation, and fibrosis, also known as Caroli's disease (Figure 63-3). Hepatic synthetic function is preserved. Portal hypertension, with associated esophageal varices and upper gastrointestinal bleeding, hepatosplenomegaly, and recurrent cholangitis are later complications of ARPKD. The North American case series showed 15–34% of patients had portal hypertension with median age of onset at 7 months and 4.6 years of life in ventilated and nonventilated patients, respectively. Severe portal hypertension required a small percentage (2.4–7%) of patients to have portocaval shunting or liver transplantation. Severity of renal disease and presence of systemic hypertension did not correlate with severity of hepatic disease (107).

### 63.3.2 Gene Mapping, Structure, Function, and Genotype–Phenotype Correlations

Initial studies excluded allelism of ARPKD to the *PKD1* locus (118,119). The first linkage studies identified the ARPKD locus, termed *PKHD1* (polycystic kidney and hepatic disease 1), at 6p21-cen (120), which was subsequently refined to a 3.8 centiMorgan (cM) segment from 6p21.1-12, without evidence of a second locus (121). Seven years later, two groups, one using a rat model system to backtrack to the human gene, the other searching within a cDNA transcription map of the *PKHD1* region, independently identified the gene within a month of each other (122,123).

The *PKHD1* gene, one of the largest disease genes in the human genome, contains a minimum of 86 exons with multiple splice forms, the longest of which spans 472 kb (Figure 63-4) (123). It encodes a 16.2 kb mRNA and is translated into a 447 kDa protein with 4074 amino acids.

Termed fibrocystin by one group and polyductin by the other, the gene has a single transmembrane domain, a large, highly glycosylated N-terminal segment containing multiple immunoglobulin-like and plexin domains, and a short C-terminal cytoplasmic tail. The function of fibrocystin is unclear, but domain analysis suggests that the protein may play a role in the regulation of cellular adhesion, repulsion, and proliferation, and/or the regulation and maintenance of renal collecting tubules and hepatic bile ducts (124). The *PKHD1* protein product localizes to primary cilia in renal tubular epithelial cells, with concentration in the basal body area (125,126).

To date, a total of 702 unique *PKHD1* mutations have been reported, and of these, 378 are classified as pathogenic (Figure 63-5) (127). Of these, 202 (53%) are missense mutations, 78 (21%) frameshift mutations, 56 (15%) nonsense mutations, and 36 (10%) splice site mutations. Large deletions of *PKHD1* have also been documented, although they make up a significantly smaller proportion of cases (128). Mutations are scattered throughout the gene without evidence of clustering. As with *PKD1* and *PKD2*, many mutations result in a truncated protein product and are unique to each family. One mutation, 107C>T (T36M), has been observed in unrelated patients of different ethnic origins and is likely a mutation “hot spot” (129). There are two founder mutations, R496X and V3471G, in the Finnish population (129).

While intrafamilial phenotypic heterogeneity and high rates of compound heterozygosity make genotype–phenotype correlation somewhat unreliable, there were some trends visible on mutation analysis. All patients carrying a truncating mutation on both parental alleles died shortly after birth regardless of the site of truncation (129). Analysis of families classified as “severe” (at least one child presenting with perinatal disease and neonatal demise) showed that 57% of the mutations detected were truncating. Families classified as “moderate” (survival or diagnosis beyond 1 month) had 70% missense mutations. However, seven missense mutations were correlated with perinatal demise (115). In some patients, only one mutant allele was identified, implying the existence of mutations within introns, regulatory elements, or larger genomic rearrangements undetectable by gene sequencing. Individuals with prominent hepatic involvement do not exhibit a specific pattern of mutation (63).

FIGURE 63-3

### 63.3.3 Laboratory, Imaging, and Histopathologic Findings

Decreased urinary concentrating ability is a universal finding in these patients. Hyponatremia (25%), elevated blood urea nitrogen (BUN) and serum creatinine (60–67%), and proteinuria (10–55%) are found on serum chemistries and urinalysis. Renal ultrasonography shows nephromegaly, increased echogenicity, loss of corticomedullary differentiation, and multiple small cysts. ARPKD can be diagnosed if the patient has characteristic renal ultrasonographic signs and is found to have hepatic fibrosis, parental consanguinity, absence of parental renal cysts, or a previous sibling diagnosed with ARPKD by renal/hepatic pathology.

Kidney specimens are spongelike in appearance, with dilated, elongated channels radiating from the medulla to the cortex at right angles to the cortical surface. Histopathologically, the cysts are derived from the distal convoluted tubules and collecting ducts, unlike ADPKD cysts, which can arise from any portion of the nephron

(107,108,130,131). Hepatic histopathology shows hepatic fibrosis and the typical ductal plate abnormality with biliary duct proliferation and dilatation.

### 63.3.4 Molecular and Prenatal Diagnosis

Molecular testing for ARPKD is clinically available and can be performed by direct sequencing of the *PKHD1* gene or by linkage analysis. As with *PKD1* and *PKD2*, interpretation of sequence results may be difficult because of the large number of private mutations and the uncertain nature of variants. With the increasing number of mutations cataloged in databases and new algorithms to determine pathogenicity of variants, the mutation detection rate now approaches 85% for the entire spectrum of ARPKD (132,133). Screening for large deletions or gross rearrangements in *PKHD1* may increase the diagnostic yield in some cases (128). *PKHD1* molecular testing has been suggested for children with isolated Caroli's disease, as one small series of 14 children with isolated

**FIGURE 63-4** Sweeney, W. E., Jr.; Avner, E. D. *Molecular and Cellular Pathophysiology of Autosomal Recessive Polycystic Kidney Disease (ARPKD)*. Cell and Tissue Research 2006, 326 (3), 675.

First described by Fanconi in 1950, nephronophthisis was previously classified together with medullary cystic kidney disease (MCKD) since both had similar presenting symptoms and renal histopathologic appearance. However, MCKD was later placed into its own category because of its autosomal dominant inheritance and later age of onset than familial nephronophthisis.

Nephronophthisis is an autosomal recessive disorder with variable presentation and considerable locus heterogeneity (140). Three different variants have been identified and are classified according to age of onset. Juvenile nephronophthisis usually presents by age 6 years, with development of ESRD by a median age of 13 years and generally between the first and second decades of life (141). Infantile nephronophthisis begins in infancy when mothers notice their babies producing an excessive number of wet diapers. The adolescent variant presents with ESRD at a median age of 19 years. In all types, progressive CRI is invariable, and anemia develops out of proportion to the degree of renal insufficiency. CRI progresses to ESRD, and if untreated, death occurs by uremia.

#### 63.4.1.1 Juvenile Nephronophthisis (MIM 256100).

Juvenile nephronophthisis is the most common of the three variants. Patients present with polyuria from tubular dysfunction and a decrease in urinary concentrating ability. Despite fluid deprivation, urine osmolality is low in these children and is not increased with the administration of vasopressin, mimicking nephrogenic diabetes insipidus (142). Hypertension is rare because of sodium wasting.

#### 63.4.1.2 Infantile Nephronophthisis (MIM 602088).

Infantile nephronophthisis was recognized as a distinct entity from other forms of nephronophthisis not only because of its extremely early presentation but also because of several phenotypic differences. Some infants present prenatally with an ARPKD-like phenotype of oligohydramnios, Potter facies, and severe respiratory insufficiency without hepatic fibrosis. Patients presenting in infancy and early childhood do not have the typical polyuria and polydipsia, but instead suffer from hypertension and hyperkalemia. *Situs inversus totalis* and cardiac defects may be present. The renal histological phenotype differs from that of juvenile nephronophthisis in that features of ARPKD (e.g. nephromegaly, microcystic cortical dilatation) are seen along with the characteristic tubular cell atrophy, interstitial cell infiltration, and fibrosis seen in nephronophthisis.

In most cases, mutations in the *NPHP2* gene cause infantile nephronophthisis. Recently, mutations in *NPHP3* and *NPHP9* have been reported in patients with very-early-onset nephronophthisis, thus establishing locus heterogeneity for infantile nephronophthisis (143,144).

#### 63.4.1.3 Adolescent Nephronophthisis (MIM 604387).

In adolescent nephronophthisis, ESRD is seen in late adolescence and young adulthood, with a reported median age of 19 years (range 4–37 years) (145). *NPHP3* was the first gene identified to cause adolescent nephronophthisis. In children with mutations in *NPHP1–4*, retinitis pigmentosa occurs in about 10% of families. However,

all patients with *NPHP5* mutations have retinitis pigmentosa (140,142).

### 63.4.2 Syndromic Forms of Nephronophthisis

An additional characteristic of nephronophthisis that distinguishes the condition from MCKD is its association with extrarenal malformations. Optic nerve colobomas, cone-shaped epiphyses, and liver fibrosis have been reported in separate kindreds. Other forms of nephronophthisis with specific extrarenal malformations have acquired syndromic nomenclature and are mentioned here.

**63.4.2.1 Joubert Syndrome (MIM 213300).** Joubert syndrome is an autosomal recessive condition characterized by congenital hypotonia, psychomotor retardation, an abnormal breathing pattern of tachypnea alternating with apnea, cerebellar ataxia, oculomotor apraxia, and most importantly, aplasia or hypoplasia of the cerebellar vermis giving the classic “molar tooth sign” on brain neuroimaging (Figure 63-6). Renal disease is present in 25% of patients with Joubert syndrome and most often manifests as nephronophthisis (146). Children typically present in the first decade of life with polyuria and polydipsia followed by CRI and ultimately renal failure by the second decade. Juvenile nephronophthisis is the most common form associated with Joubert syndrome, but infantile and adolescent onset nephronophthisis can occur.

At least 10 different genes are known to cause Joubert syndrome, and other loci are yet to be determined. Mutations in *AHI1*, *NPHP6*, *MKS3*, and *CC2D2A* each account for approximately 10% of cases (147–150). About 1–2% of patients have a homozygous *NPHP1* deletion (148).

#### 63.4.2.2 Senior-Løken Syndrome (MIM 266900).

Also known as Senior syndrome or renal-retinal syndrome, this disorder is a combination of nephronophthisis and degeneration of the retinal pigment epithelium and accounts for approximately 10–15% of all cases of nephronophthisis. Renal symptoms and histopathology are identical to that of isolated nephronophthisis, including the variability in age of onset. Similarly, onset of ocular pathology varies from birth to childhood. Newborns present with Leber’s congenital amaurosis, characterized by visual inattention, nystagmus, near-absent pupillary reaction, and blindness or severe visual impairment. Older children present with nyctalopia (night blindness), then develop progressive loss of bilateral peripheral vision. Color perception and central visual acuity are preserved until end-stage disease, which typically occurs in adolescence, although there is one report of an adult patient with some preservation of visual fields and acuity (151). Fundoscopic examination reveals attenuation of blood vessels and pallor of the optic disk without the “bone spicule” retinal pigmentary abnormalities typically seen in retinitis pigmentosa.

In the majority of cases, Senior-Løken syndrome is caused by mutations in *NPHP5*, but mutations in *NPHP1*,

FIGURE 63-6

including the classic 290 kb deletion, *NPHP2*, *NPHP3*, and *NPHP4* have been reported (139,142,145,152–154). In addition, mutations in *NPHP6* cause 20% of cases of Leber congenital amaurosis, which is characterized by early onset of severe vision impairment from retinitis pigmentosa, without renal disease (155,156). The frequency of retinitis pigmentosa in Senior–Løken syndrome varies with the gene involved, from 6% with *NPHP1* to 100% with *NPHP5* and *NPHP6* (142).

#### 63.4.2.3 Meckel–Gruber Syndrome (MIM 249000).

Meckel–Gruber syndrome is a severe, perinatally lethal, multiple congenital anomaly syndrome with an estimated incidence between 1:140,000 to 1:13,250 births (157). Infants have bilaterally enlarged, cystic kidneys and hepatic ductal plate dysplasia, biliary proliferation, and fibrosis similar to those with ARPKD. Renal cysts involve both the cortex and the medulla. Cortical cysts tend to be small, thin walled, and surrounded by normal glomeruli, while medullary cysts are larger, up to several millimeters in diameter, and separated by thick fibromuscular walls (131). Central nervous system malformations are severe. Posterior encephalocele is the most common malformation, while aplasia or hypoplasia of various central nervous system (CNS) structures, such as the cerebellum, cerebrum, corpus callosum, and optic or olfactory tracts, are present in other patients. Preaxial or postaxial polydactyly is another cardinal feature of the syndrome. Prenatal diagnosis of Meckel–Gruber syndrome can be made with transvaginal ultrasound as early as 10–12 weeks gestational age.

The mode of inheritance is autosomal recessive, and locus heterogeneity has been well established. Mutations in *MKS1*, *TMEM216*, *MKS3/TMEM67*, *NPHP6/CEP290*, *NPHP8/RGRIP1L*, *NPHP3*, and *CC2D2A* all have been reported to cause Meckel–Gruber syndrome. Many of these genes overlap with those causing Joubert syndrome, suggesting that these disorders form a continuum of phenotypic variation rather than separate entities (158).

#### 63.4.2.4 Cogan-Type Oculomotor Apraxia (MIM 257550).

Patients with Cogan-type oculomotor apraxia suffer from an inability to make smooth voluntary horizontal eye movements and initiate horizontal saccades. In order to bring objects into view, they must make quick, jerking movements of their heads. Involuntary horizontal eye movements are not impaired, indicating that the oculomotor nerves are capable of firing normally. Nephronophthisis has been reported in association with this disorder, but unlike Joubert syndrome, these patients do not have the molar tooth sign or retinitis pigmentosa.

Mutations in *NPHP1* and *NPHP4* have been found in patients with Cogan-type oculomotor apraxia and nephronophthisis. Homozygosity of the classic *NPHP1* deletion has been reported in one patient, while another patient was found to have the classic deletion of one allele and an inactivating splice junction point mutation of the other (159). Homozygosity for a frameshifting 3272delT mutation in *NPHP4* has also been documented (160).

**63.4.2.5 Mainzer–Saldino Syndrome.** The association of nephronophthisis with cone-shaped epiphyses has been described. In addition, patients with this syndrome can also develop retinal degeneration and cerebral ataxia (161).

#### 63.4.3 Gene Mapping, Structure, Function, and Genotype–Phenotype Correlations

At least nine different genes are known to be associated with nephronophthisis in addition to those responsible for the syndromic forms of nephronophthisis (Table 63-2). The most common mutation in patients with nephronophthisis is a homozygous deletion of *NPHP1*, which accounts for 21% of cases (142). The remaining genes each comprise <3% of cases, and the mutation is unknown in 70%.

### TABLE 63-2

Gene (Protein)	Chromosome	Phenotype (Median Age at ESRD)	Extrarenal Symptoms	Mutation Frequency (%)	Intervention
<i>NPHP1</i> (nephrocystin-1)	2q13	NPHP (13 years)	RP (10%), OMA (2%), JS (rarely)	23.4, homozygous deletion 2.1, point mutation	Investigative
<i>NPHP2/INVS</i> (inversin)	9q31	Infantile NPHP (<5 years)	RP (10%), LF, <i>situs inversus</i> , VSD	1.4	Nephrectomy
<i>NPHP3</i> (nephrocystin-3)	3q22	Infantile and adolescent NPHP	LF, RP (10%), <i>situs inversus</i> , MKS	0.7, if truncating mutation infantile form	Nephrectomy
<i>NPHP4</i> (nephrocystin-4)	1p36	NPHP (21 years)	RP (10%), OMA, LF	2.6	Nephrectomy

**63.4.3.1 NPHP1.** The first gene locus for nephronophthisis was mapped to 2p by linkage analysis of 22 multiplex families (162). The locus was refined first to 2q13, then with fine mapping techniques to a 2Mb critical region (163–167). An approximately 250kb deletion was discovered in 80% of familial cases of nephronophthisis mapping to the 2q13 locus (167). Two ORFs were identified within the deleted region, one encoding a small 148 amino acid protein involved in cellular trafficking and the other encoding a then-uncharacterized protein that was eventually shown to be mutated in patients with nephronophthisis (168,169).

The *NPHP1* protein, named nephrocystin-1, contains 20 exons spanning 83kb of the genome, and encodes a 4.5kb mRNA. The predicted protein is 732 amino acids long and weighs 83kDa. It contains coiled-coil domains and an *Src*-homology 3 domain (SH3), both of which are protein–protein interaction motifs (Figure 63-7). SH3 domains are typically found on “adapter” proteins that bring other proteins together. Through the yeast 2-hybrid system, nephrocystin-1 was shown to bind the focal adhesion complex protein p130cas. Immunofluorescence demonstrated that nephrocystin-1 and p130cas co-localize in vivo at focal adhesions of the basolateral cell membrane (170,171). p130cas is a cytosolic protein involved in the focal adhesion complex, which mediates signal transduction from the extracellular matrix to the nucleus (172). Nephrocystin-1 was also found to co-localize with E-cadherin at adherens junctions (173) and with  $\beta$ -tubulin in the primary cilia of renal cells, specifically, at the transition zone (174,175). In addition, it interacts with other nephrocystin proteins and Joubertin to form a multiprotein complex (145,160,174,176). These findings, along with similar results from PKD1, PKD2, and PKHD1 localization, indicate the important role of cilia, cell–cell, and cell–matrix interactions in inherited kidney disease (142,177,178).

As stated earlier, more than 80% of patients with juvenile nephronophthisis have a homozygous 290kb deletion of *NPHP1* (170,179). The gene is flanked by two 330kb inverted repeats, with two nearby 45kb repeats, making the segment prone to unequal homologous recombination and intrachromosomal loop excision, creating an interstitial deletion (180) (Figure 63-7).

Nonsense, frameshift, and splice site mutations in *NPHP1* have also been documented, and all likely result in loss-of-function of nephrocystin-1 (181). Only one missense mutation, 1024G>A, has been reported, leading to a nonconservative amino acid change in a residue that is conserved in mouse and dog *NPHP1* (182).

Why some patients with the classic *NPHP1* deletion have only renal manifestations while others have Senior–Løken syndrome, Joubert syndrome, or Cogan-type oculomotor apraxia is not clear. There may be other genes within the deleted region or around the deletion boundaries that are responsible for extrarenal disease. Another possible explanation is triallelic inheritance, in which a mutation in another gene, in addition to deletion of *NPHP*, is required for multisystemic disease. Other theories include subtle rearrangements of the break points undetectable by haplotype analysis, or disruption of enhancer sequences altering expression of genes outside the deletion region.

**63.4.3.2 NPHP2.** Linkage analysis in an inbred Bedouin family with infantile nephronophthisis localized the gene locus to a 12.9cM region at 9q22–q31 (183). The discovery of mutations of *inversin* in the *invlinv* mouse, which has enlarged, cystic kidneys, *situs inversus*, and histopathologic findings similar to nephronophthisis, and the location of human *inversin* within the NPHP2 critical region, strongly suggested that *inversin* was the candidate gene. Confirmation came when mutational analysis in seven families with infantile nephronophthisis showed recessive mutations in the gene (174), which was then named *NPHP2* or *INVS*.

*NPHP2* is a 17-exon gene spanning 100kb of genomic DNA, encoding a 1065 amino acid protein, nephrocystin-2/inversin, which is conserved from the zebrafish to the mouse. It has a highly conserved N-terminal domain containing 16 tandem ankyrin repeats, a split nuclear localization signal, two calmodulin-binding IQ domains, and two “destruction” or D boxes that bind a protein involved in the anaphase-promoting complex, a cell-cycle regulatory ubiquitin ligase that regulates cellular transition from metaphase to anaphase and mitosis to G<sub>1</sub>. Inversin co-localizes with nephrocystin-1 in the primary cilia of renal tubular epithelium, connecting it with other proteins that have a role in cilia formation, maintenance,

FIGURE 63-7

and intraflagellar transport (174) (Figure 63-8). In addition, cell-cycle-dependent expression of *NPHP2* and its role in the Wnt signaling pathway support the hypothesis that nephrocystin-2/inversin is involved in the maintenance of normal planar cell polarity (184,185).

Frameshift, missense, and splice site mutations have all been reported in *NPHP2*, and most mutations result in protein truncation. Five recurrent mutations have been found in unrelated families: R899X, R907X, Q485fsX509, Q671X, and E970fsX971 (144,181). No clear genotype–phenotype correlations have been established. In a cohort of seven families with *NPHP2* mutations, one patient with homozygous missense mutations did not have onset of ESRD until age 5 years, but neither did children of a family with compound heterozygous truncating mutations. The patient with *situs inversus totalis* had homozygous truncating R603X mutations and was the only patient with mutations in both alleles that removed all domains C-terminal to the ankyrin repeats, including the nuclear localization domains (174).

**63.4.3.3 NPHP3.** Examination of a large, inbred Venezuelan family with nephronophthisis indicated, at the time, that their disease was distinct from juvenile and infantile nephronophthisis on the basis of both the later age of onset and the gene locus. A total genome scan followed by higher resolution haplotype analysis mapped the family's locus to a 3.3 Mb interval at 3q22 (186,187). Seven genes with known function and eight expressed sequence tags (ESTs) were found within this interval.

The mapping of several families with Senior-Løken syndrome to the same region narrowed the candidate

genes to five ESTs, and sequencing revealed mutations in a 40.5 kb gene that was named *NPHP3*. *NPHP3* is composed of 27 exons and encodes a 3990 nucleotide mRNA, which is translated into a 1330 amino acid cytosolic protein product called nephrocystin-3. The protein has an N-terminal coiled-coil region and a tubulin-tyrosine ligase domain and interacts with nephrocystin-1 and nephrocystin-2/inversin (145,188) (Figure 63-9). In embryonic mice, the mRNA is expressed first in the node during gastrulation, then in the brain, retina, liver and biliary tract, renal tubules, and respiratory epithelium. Mutations in the murine ortholog *Nphp3* produce the *pcy* mouse mutant, which has cystic kidney disease due to a hypomorphic *Nphp3* allele (145). Interestingly, treating the *pcy* mouse with a vasopressin-2 receptor antagonist has been shown to ameliorate disease by lowering renal cAMP levels (136). This discovery may lead to future therapeutic interventions.

The phenotypic spectrum associated with *NPHP3* mutations has broadened as more cases are amassed and now includes infantile and adolescent nephronophthisis, nephronophthisis with liver fibrosis, nephronophthisis with retinitis pigmentosa, and embryonic patterning defects. With regard to genotype–phenotype correlations, truncating and splice site mutations in *NPHP3* produce a more severe phenotype similar to Meckel–Gruber syndrome, whereas missense and other nontruncating mutations are associated with milder and later-onset disease (139,144).

**63.4.3.4 NPHP4.** After the discovery of *NPHP1*, *NPHP2*, and *NPHP3*, there continued to be kindreds that did not map to any of these loci (189). Those

FIGURE 63-8

families were gathered, and linkage analysis mapped them to a 2Mb region within 1p36.31 (153). Higher resolution haplotype mapping narrowed the region to a 700kb interval containing six genes. Two groups identified mutations in the same gene and named it *NPHP4* (154,160).

*NPHP4* is a large, 30 exon gene that spans 130kb and encodes nephrocystin-4/nephroretinin, a 1426 amino acid protein product that has no known homologs in the human genome (Figure 63-10). It is a highly conserved protein, with orthologs found in the mouse, cow, pig, zebrafish, *Xenopus*, *Ascaris*, and *Caenorhabditis elegans*. The mouse ortholog shares 78% sequence identity, while the *C. elegans* ortholog has 24% identity with the human sequence. Domain analysis shows a putative nuclear localization signal, an acidic domain, and an SH3 domain, the latter two also being features of nephrocystin-1 (154). Nephrocystin-4 forms a complex with nephrocystin-1 and other proteins including p130Cas and Pyk2. It localizes to primary cilia, basal bodies, and centrosomes, consistent with the pathogenic mechanism of cystogenesis ascribed to other nephrocystin proteins (190). In addition, nephrocystin-4 localizes to the connecting cilium of photoreceptor cells where it interacts

with RPGRIPI (retinitis pigmentosa GTPase regulator interacting protein 1), deficiency of which is responsible for Leber congenital amaurosis (191).

A recent mutational analysis of *NPHP4* in 250 patients with nephronophthisis identified 23 novel sequence variants in 26 (10%) different patients (192). Of the six patients who had either homozygous or compound heterozygous mutations, 5/8 mutations (63%) were thought to be loss-of-function or truncating mutations. In the 20 patients with only one sequence variant detected, only 1 was a likely loss-of-function mutation. No genotype-phenotype correlations were recognized.

Previously reported mutations in *NPHP4* have included nonsense, missense, frameshift, and splice site mutations, most resulting in a truncated protein (154,160). Three kindreds with no extrarenal involvement were found to have homozygous missense mutations, G754R, R848W, and F991S, indicating a possible genotype-phenotype correlation between isolated nephronophthisis and missense mutations (154,160).

**63.4.3.5 NPHP5.** *NPHP5*, also called *IQCB1*, spans 65.7kb and contains 15 exons. The first two exons are not translated. *NPHP5* encodes nephrocystin-5, a 598 amino acid protein that is ubiquitously expressed in fetal

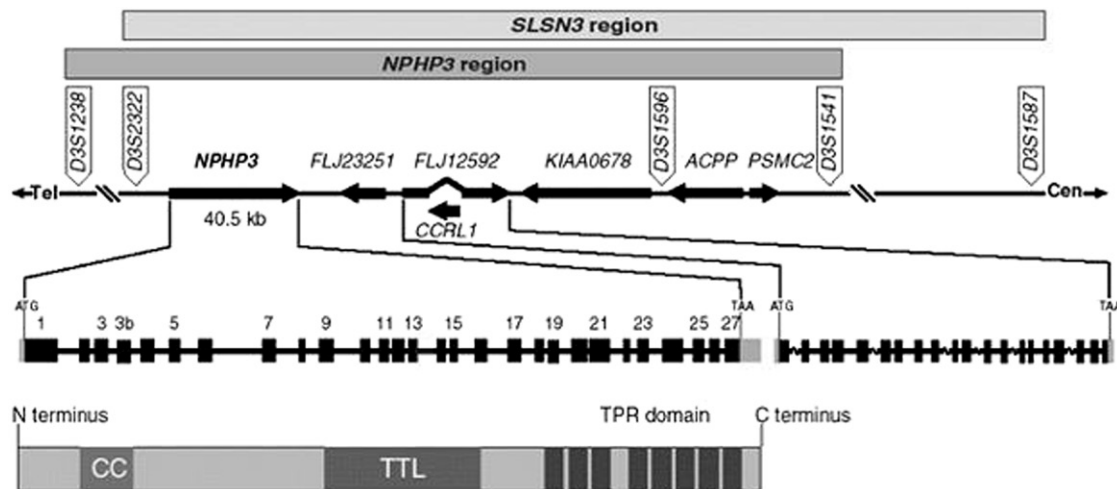

FIGURE 63-9

FIGURE 63-10 Reinhardt, Lehrack, S., et al. Mutational analysis of the *NPHP4* gene in 250 patients with nephronophthisis. Human Mutation 2005, 25 (4), 411.

and adult tissues (193). It has a coiled-coil domain and two IQ calmodulin-binding regions. Nephrocystin-5 directly interacts with calmodulin and forms a complex with retinitis pigmentosa GTPase regulator (RPGR) that localizes to primary cilia in renal epithelial cells and their homologous structures in the retina, photoreceptor connecting cilia (193). Mutations in *NPHP5* cause Senior-Løken syndrome, which is characterized by nephronophthisis and early-onset retinitis pigmentosa. All the eight mutations originally described resulted in protein truncation; no missense mutations were found (193). Most of the affected individuals had homozygous mutations.

**63.4.3.6 NPHP6.** *NPHP6*, also known as *CEP290*, spans 93.2kb and contains 55 exons. It encodes nephrocystin-6, a 290kDa protein of 2479 amino acids with 13 putative coiled-coil domains, a region with homology to structural maintenance of chromosomes (SMC) chromosome segregation ATPases<sup>14</sup>, a bipartite nuclear localization signal (NLS\_BP), six RepA/Rep<sup>+</sup> protein KID motifs (KID), three tropomyosin homology domains and an ATP/GTP-binding site motif A (P-loop) (149). Nephrocystin-6 localizes to centrosomes in renal epithelial cells during interphase and to connecting cilia of photoreceptors. It interacts with nephrocystin-5 and ATF4, a transcription factor involved in the regulation of the cell cycle and in cAMP-dependent renal cyst formation (136,149,158). Mutations in *NPHP6* can produce exclusive cystic renal disease, syndromic forms of nephronophthisis such as Joubert syndrome and Meckel-Gruber syndrome, as well as Leber congenital amaurosis. The nine initially reported mutations were all nonsense or frameshift mutations (149).

**63.4.3.7 NPHP7.** *NPHP7* is also known as *GLIS2* and contains six exons spanning more than 7.5kb. The protein nephrocystin-7 or “Gli-similar protein 2” is highly expressed in the kidney and localizes to primary cilia of renal epithelial cells and nuclei (194,195). The *GLIS2* protein is related to the Gli transcription factor, suggesting a possible link between cyst formation and the sonic hedgehog signaling network (142). Mutations in *NPHP7* were first reported in a consanguineous Oji-Cree kindred (195). Affected members had a homozygous transversion (IVS5 + 1G > T) affecting a splice donor site. Other than this index family, mutations in *NPHP7* appear to be a rare cause of nephronophthisis.

**63.4.3.8 NPHP8.** *NPHP8*, or *RPGRIP1L* as it is also known, is composed of 27 exons, the last of which is noncoding, and extends over 103.2kb. The encoded protein, nephrocystin-8/RPGRIP1L (retinitis pigmentosa GTPase regulator interacting protein 1-like), is ubiquitously expressed in human embryonic and fetal tissues. It contains five coiled-coil domains, a C-terminal region homologous to the RPGR-interacting domain of RPGRIP1, and a central region with two protein kinase C conserved region 2 (C2) motifs. Nephrocystin-8 co-localizes with nephrocystin-4 and nephrocystin-6 to

basal bodies, centrosomes, and primary cilia of renal tubular cells (196,197). The spectrum of phenotypic variability observed in individuals with *NPHP8* mutations can be explained in part by the type of mutation. Homozygous truncating mutations of *NPHP8* produce Meckel-Gruber syndrome or similar severe phenotypes, whereas the presence of at least one missense mutation causes milder and later-onset disease (139,196). Heterozygous and homozygous missense mutations as well as frameshift and splice site mutations have all been reported in individuals with Joubert syndrome (196–198). Other extrarenal features may include polydactyly, liver fibrosis, pituitary agenesis, and partial growth deficiency.

**63.4.3.9 NPHP9.** *NPHP9*, also known as *NEK8*, is an extremely rare cause of nephronophthisis. In a study of 588 patients with nephronophthisis, only three missense mutations were identified in *NPHP9*, and in one of these individuals, a homozygous mutation in *NPHP5* was also present, suggesting possible oligogenic inheritance (143). Like all known nephrocystin proteins, nephrocystin-9 localizes to primary cilia of renal tubular epithelial cells (143,199). It has been shown to interact with polycystin-2, and in mouse models, mutations in *Nek8* cause increased expression of polycystin-1 and polycystin-2 (199). Nephrocystin-9/NEK8 is also thought to play a role in cell cycle regulation (142).

In general, other than the specific genotype–phenotype correlations mentioned earlier, the phenotypic variation in nephronophthisis does not appear to be attributable solely to the gene involved or the type of mutation. Genetic modifiers have been shown to play a role. The R830W allele of the *AHI1* gene was found more frequently in patients with nephronophthisis and retinal degeneration than in those with nephronophthisis without retinal degeneration (25% compared to 1.8%,  $P = 5.36 \times 10^{-6}$ ), equaling a relative risk of 7.5 (200). This association was true regardless of the primary mutation. Similarly, the Thr229 variant of the *RPGRIP1L* gene was shown to be associated with retinitis pigmentosa in a small cohort with nephronophthisis (201). Other factors may become apparent as the mechanism of disease is further elucidated.

#### 63.4.4 Laboratory, Imaging, and Pathologic Findings

A complete blood count reveals severe microcytic, hypochromic, hypoproliferative anemia due to low erythropoietin secretion. Creatinine clearance is decreased, while serum creatinine and BUN are increased. Urine osmolality following water deprivation/dDAVP administration is inappropriately low compared to serum osmolality and reflects loss of urinary concentrating ability (also known as nephrogenic diabetes insipidus). Proteinuria and pyuria are rare. Renal ultrasonography shows normal to decreased renal size, increased

echogenicity, and diminished corticomedullary differentiation. Although corticomedullary cysts may be present, it is important to note that their presence is not necessary for diagnosis. Renal biopsy shows a characteristic set of histopathologic findings: disorganized tubular basement membranes, tubular atrophy with cyst formation, interstitial lymphohistiocytic infiltration, and periglomerular and interstitial fibrosis. Patients with nephronophthisis should also be screened for ocular involvement with fundoscopic examination and an electroretinogram if Senior-Løken syndrome is suspected. A brain MRI may show the molar tooth sign in patients with Joubert syndrome.

### 63.4.5 Molecular and Prenatal Diagnosis

Given the high degree of genetic heterogeneity and phenotypic variation, it may not be clear which gene to test first. Furthermore, molecular genetic testing is not available on a clinical basis for all genes associated with nephronophthisis. An algorithm has been suggested to aid in decision making (158). In children less than 5 years of age, testing for mutations in *NPHP2* should be sought first. In those older than 5 years, testing should begin with *NPHP1*, as the classic homozygous deletion accounts for a significant number of cases of nephronophthisis. If no mutations are detected, testing of other genes is dictated by the nature of the extrarenal complications. It has recently been shown that high throughput sequencing is an efficient method to detect rare mutations (202). Analysis of 18 genes associated with nephronophthisis and its variant forms in 120 patients led to a molecular diagnosis in 30 (25%). This and other types of advanced diagnostic techniques will become more widely available for clinical purposes in the future. Of note, no mutation is identified in over two-thirds of patients, implying that other genes are yet to be discovered. In all cases, a careful family history should be elicited, looking in particular for consanguinity or a history of early death or renal disease.

### 63.4.6 Management

There is currently no therapy for the underlying disease or the ophthalmologic and neurologic manifestations. The anemia responds to administration of erythropoietin. Supportive care should be given for complications of renal insufficiency such as acidosis, electrolyte disturbances, and hypovolemia. Periodic monitoring of renal function is necessary so that dialysis and enrollment in transplantation registries can be initiated at onset of ESRD. Analysis of the North American Pediatric Renal Trials and Collaborative Studies database demonstrates that nephronophthisis transplant recipients have excellent outcomes that are better than those of the general pediatric transplant population (203).

## 63.5 MEDULLARY CYSTIC KIDNEY DISEASE

### 63.5.1 Clinical Features and Natural History

The first family with MCKD was likely reported in 1966 (204). Patients can present with polyuria, polydipsia, or isosthenuria, which are the same symptoms of juvenile nephronophthisis. Unlike nephronophthisis however, MCKD is dominantly inherited and has adult onset of disease. In addition, most MCKD patients present with hypertension (40%), hyperuricemia (36%), gout (20%), or microalbuminuria (5%), which are not found in nephronophthisis (205,206). A bimodal pattern is observed in the age of onset of disease and ESRD, with one peak in the third to fourth decade of life and another in the fifth to sixth decade of life. This pattern reflects the difference in phenotype of the two loci identified for MCKD. MCKD1 generally presents later while MCKD2 presents earlier, although there is some overlap.

Regardless of the age of presentation, disease progresses rapidly: the average interval from diagnosis to ESRD is 5 years. Hyperuricemia tends to worsen as renal function worsens (207). Hypotension replaces hypertension in later stages of disease as patients lose renal concentrating capacity and become hyponatremic. If treatment via dialysis or transplant is not initiated, death occurs by uremia and renal failure.

### 63.5.2 Gene Mapping, Structure, Function, and Genotype–Phenotype Correlations

**63.5.2.1 MCKD1 (MIM 174000).** Initial studies excluded linkage to the *NPHP1* locus (208). Linkage analysis in a Cypriot family placed a locus for MCKD, later termed *MCKD1*, with the discovery of a second locus, at 1p21 (209). The critical region was narrowed to a 3.3 Mb region by fine mapping (210). Several candidate genes in the region, the natriuretic peptide receptor A (NPR-A) and the rhesus blood group B glycoprotein genes, were excluded when no mutations were found in either (205,211,212). The critical region was further narrowed to a 2.1 Mb interval (206). Mutational analysis of 37 genes within the critical region was performed, and three sequence variations were identified in three different genes, each segregating within a particular family (213). Thus, a single causative gene remains to be determined. Alternatively, multiple genes may be involved.

**63.5.2.2 MCKD2 (MIM 603860).** Several MCKD kindreds did not show linkage to the *MCKD1* critical region, and subsequent study of an Italian pedigree led to the identification of 16p12 as a second MCKD locus (214,215). The Italian MCKD2 family had earlier onset of disease, isosthenuria, and more severe hyperuricemia and gout, but another MCKD2 family did not have isosthenuria, hyperuricemia, or gout (216). Mapping of a

family with familial juvenile hyperuricemic nephropathy (FJHN) and medullary cysts to 16p12 suggested that MCKD2 and FJHN were allelic and narrowed the critical interval to a 1.3 Mb region (217).

Pathogenic mutations in the uromodulin gene, *UMOD*, were found in families with FJHN, and sequencing of *UMOD* in patients with MCKD2 revealed mutations as well (218). The uromodulin gene has 12 exons (10 coding) spanning 18.6 kb of the human genome. It is transcribed into a 2.4 kb mRNA, which is translated into a 640 amino acid protein that is also known as Tamm-Horsfall protein. Uromodulin/Tamm-Horsfall protein (UMOD/THP) is expressed in the epithelium of the thick ascending loop (TAL) of Henle and the early distal convoluted tubules (219). UMOD is anchored to the plasma membrane via a glycosyl phosphatidylinositol linkage, and is secreted via cleavage of the anchor. It contains two calcium-binding epidermal growth factor (cbEGF) domains and a zona pellucida (ZP) domain that facilitates its polymerization into fibers that forms a gel impermeable to water but allows ion flux (220) (Figure 63-11). Thus, uromodulin is thought to impart to the TAL its water impermeability, and therefore, enable the kidney to concentrate urine. It is also hypothesized to inhibit renal stone formation and protect against UTI and ischemia (221–224).

All the known *UMOD* mutations are missense or in-frame deletions/insertions in exon 4, which encodes the cbEGF domains. A family with homozygous mutations in *UMOD* was observed to survive to adulthood but have more severe hyperuricemia and faster progression to ESRD (225).

An interesting finding that may cast light on the pathogenesis of MCKD is that the majority of mutations affect conserved cysteine residues (219,226,227). Since

no free sulfhydryl groups are found on uromodulin, these mutations likely alter proper disulfide bonding and protein folding (228). Misfolded endoplasmic reticulum (ER) proteins tend to aggregate within the ER and are not secreted, a finding confirmed for mutated uromodulin (220,226). Decreased UMOD secretion in the TAL of the nephron may increase water permeability, and therefore, decrease renal concentrating ability, explaining the isosthenuria seen in patients with MCKD2. Increased salt and water excretion leads to compensatory distal convoluted tubule and collecting duct reabsorption and secondary urate reabsorption, leading to hyperuricemia. Tubular cells undergo apoptosis because of accumulation of undegradable, misfolded uromodulin (229). The body mounts an inflammatory response to the release of UMOD into the interstitium, eventually leading to fibrosis.

**63.5.2.3 Other Loci.** Linkage analysis of MCKD kindreds uncovered families that mapped neither to the *MCKD1* locus nor to *MCKD2*, suggesting the existence of more loci for MCKD (214,230).

### 63.5.3 Imaging and Histopathologic Findings

Renal ultrasonography shows normal to decreased renal size and reduced cortical thickness. Although bilateral corticomedullary or medullary cysts may be present (40%), they are not necessary for diagnosis, nor are they pathognomonic for MCKD (207). Histopathologic findings of renal biopsies are indistinguishable from biopsies of patients with nephronophthisis: disorganized tubular basement membranes, tubular atrophy with cyst formation, interstitial lymphohistiocytic infiltration, and periglomerular and interstitial fibrosis.

FIGURE 63-11

### 63.5.4 Molecular and Prenatal Diagnosis

Diagnosis is made primarily via a combination of suggestive clinical features, imaging, and (if available) renal histopathologic findings. Since no specific gene has been identified for MCKD1, testing of at-risk individuals requires a family with several affected members and sufficient size in order for linkage analysis to have sufficient power. Confirmatory molecular testing is available on a commercial basis for MCKD2. Prenatal testing or testing of presymptomatic children is not recommended for a disease that is both treatable and does not present until adulthood.

### 63.5.5 Management

Since there is no therapy for the underlying disorder, treatment is limited to supportive care. Gout and hyperuricemia are controlled with allopurinol. Interval assessment of renal function should be performed to detect onset of ESRD, when dialysis and renal transplantation should be initiated. MCKD must be excluded in family members who wish to be kidney donors. Outcomes of renal transplantation are excellent; the graft kidney does not develop cystic disease (231).

## 63.6 MULTICYSTIC DYSPLASTIC KIDNEY DISEASE (MKD)

By ultrasound, congenital MDK consists of cysts of various sizes with loss of lobar organization. Microscopically, there is loss of normal structure, with the presence of primitive ductules and cartilage, suggesting aberrations in renal differentiation. Dysplasia can result in cysts that are solid or cystic, large or small. Function is variable (232).

MDK usually presents as an abdominal mass in the newborn period. Other significant manifestations are uncommon and include flank pain, urinary frequency, dysuria, failure to thrive and UTI.

Most cases of MKD occur sporadically. However, a number of syndromes can have MKD as their renal manifestation. These include Meckel–Gruber syndrome, Jeune asphyxiating thoracic dystrophy, Zellweger syndrome, VACTERL association, brachio–oto–renal syndrome, Williams syndrome, Beckwith–Wiedemann syndrome and certain chromosomal trisomies.

## 63.7 GENETIC SYNDROMES WITH CYSTIC RENAL DISEASE AS A MAJOR COMPONENT

### 63.7.1 Tuberous Sclerosis Complex (MIM 191100, 613254)

Tuberous sclerosis complex is a neurocutaneous disorder with an incidence of 1 in 5000 to 10,000 live births (233) and is characterized by the involvement of many organ

systems including benign hamartomas of the brain, eye, heart, lung, liver, kidney, and skin (for more information, please refer to the chapter on Phakomatoses).

Renal manifestations include angiomyolipomas, which are the most common, followed by renal cysts and lymphangiomas. Angiomyolipomas are at increased risk of bleeding, especially with progressive enlargement. Renal cell carcinoma develops in 1–2% of patients. The Consensus Conference recommended the following surveillance imaging studies for patients with TSC (234). Renal ultrasonography should be performed at the time of diagnosis to ascertain the presence or absence of the polycystic variant of TSC or angiomyolipomas. All children with TSC should have screening with renal ultrasonography every 1–3 years (3 years if no prior lesions are seen on imaging). If malignant transformation or the development of large angiomyolipomas (greater than 3–4 cm) is detected, abdominal CT or MRI should be performed to evaluate the abnormalities. Interventional radiology can be consulted for treatment of the lesions greater than 3–4 cm to prevent hemorrhage.

Tuberous sclerosis complex is inherited in an autosomal dominant manner with variable expression. Two genes are known to cause the disorder: *TSC1*, located on chromosome 9q34, and *TSC2*, located on chromosome 16p13.3, which lies in close proximity to the *PKD1* gene. A contiguous gene deletion syndrome involving *TSC2* and *PKD1* results in a combined phenotype of tuberous sclerosis and ADPKD. *TSC1* encodes hamartin, and *TSC2* encodes tuberin. The two proteins interact to form a complex. In affected individuals meeting definite clinical criteria, 70–80% have an identifiable mutation in one of these two genes, with *TSC2* being more frequently implicated (235). Sequence variants account for the majority of mutations, but large deletions and rearrangements have also been reported in both genes (236). With regard to genotype–phenotype correlations, individuals with a *TSC1* mutation appear to have milder disease than those with a *TSC2* mutation. One study showed decreased frequency of seizures and mental retardation, fewer subependymal nodules and cortical tubers, milder kidney involvement, absence of retinal hamartomas, and less severe facial angiofibroma in patients with *TSC1* mutations (237). In addition, mutations in familial *TSC2* cases appear to be associated with less severe clinical manifestations than de novo *TSC2* mutations (238).

### 63.7.2 Bardet–Biedl Syndrome (MIM 209900)

Bardet–Biedl syndrome (BBS) is a genetically heterogeneous disorder with 14 gene loci identified to date (Table 63-3). It is usually inherited in an autosomal recessive manner, but some forms have a unique triallelic inheritance pattern requiring recessive mutations at one locus and an additional mutation at a second locus. Owing to considerable phenotypic heterogeneity,

TABLE 63-3

Gene	Locus
<i>BBS1</i>	11q13
<i>BBS2</i>	16q21
<i>BBS3/ARL6</i>	3p12–q13
<i>BBS4</i>	15q22.3–q23
<i>BBS5</i>	2q31
<i>BBS6/MKKS</i>	20p12
<i>BBS7</i>	4q27
<i>BBS8/TTC8</i>	14q32.1
<i>BBS9/B1</i>	7p14
<i>BBS10</i>	12q21.2
<i>BBS11/TRIM32</i>	9q31–34.1
<i>BBS12</i>	4q27
<i>BBS13/MKS1</i>	17q23
<i>BBS14/CEP290</i>	12q21.3

a classification system has been proposed in which a minimum of four major criteria are required for diagnosis. The major diagnostic criteria are learning disability (62–87%), rod–cone dystrophy (92–100%), postaxial polydactyly (58–74%), truncal obesity (72–96%), hypogonadism in males (74–96%), and renal anomalies (46–95%). Speech deficit (54%); motor and speech delay (50%); hypertension (50%); ataxia (40%); “difficult,” immature, volatile behavior with lack of inhibition and easy frustration (33%); dental crowding (27%); and asthma (25%) are other common features (239). Molecular diagnostic testing is commercially available.

BBS shares some features of nephronophthisis, with polyuria, polydipsia, nyctalopia progressing to total blindness in the second decade of life, hepatic fibrosis, and chronic renal failure reported in some patients. Renal pathology is sometimes indistinguishable from nephronophthisis and MCKD. Progression to ESRD, however, is rare. Structural renal anomalies include cortical cysts, calyceal blunting, hydronephrosis, vesicoureteral reflux with recurrent UTI, renal dysplasia, and fetal lobulation (240).

A possible link to inversin (*NPHP2*), cilia, and cell-cycle regulation was discovered when the *BBS8* protein was found to localize to centrosomes and co-localize with tubulin. Furthermore, patients with homozygous mutations of *BBS8* were found to have randomization of body situs (241). For the most part, BBS proteins localize to cilia, centrosomes, or basal bodies (241–246).

### 63.7.3 Jeune Asphyxiating Thoracic Dysplasia (MIM 208500) and the Short-Rib Polydactyly Syndromes

Patients with asphyxiating thoracic dysplasia (ATD) have extremely narrow, constricted thoracic cages caused by shortened, horizontal ribs. Death often occurs in infancy because of severe pulmonary hypoplasia as a consequence of the small chest cavity. Survivors face recurrent

pneumonia and the possibility of respiratory failure incurred by restrictive lung disease. Long bones and phalanges are shortened and some patients have postaxial polydactyly of the hands and/or feet. Radiographs show short ribs with irregular costochondral junctions, hypoplastic iliac wings with trident-shaped acetabulae, transient irregularity of epiphyses and metaphyses, and cone epiphyses of the phalanges. Short stature and relative size of the thoracic cage improve with age, but children also develop biliary ductal plate malformations and hepatic fibrosis, pancreatic cysts and fibrosis, and polycystic kidneys. Renal histopathology shows cystic renal tubular dysplasia and possibly disorganized tubular basement membranes, tubular atrophy, and interstitial infiltration and fibrosis seen in nephronophthisis. Interestingly, some patients with ATD are affected with tapetoretinal degeneration and situs inversus, which are also seen in patients with nephronophthisis (247,248). Currently, two causative genes, *IFT80* and *DYNC2H1*, are associated with ATD. Like the nephronophthisis and BBS genes, *IFT80* and *DYNC2H1* play a role in ciliary and/or microtubular function.

ATD belongs to the short-rib dysplasia family of skeletal dysplasias, which includes the four neonatal lethal short-rib polydactyly (SRP) syndromes, Ellis–van Creveld dysplasia, and Barnes thoracolumbar pelvic dysplasia. Infants with the SRP syndromes are hydropic and die in the perinatal period from respiratory insufficiency. Cystic renal disease is present in all four types of SRP. All have CNS malformations (Dandy–Walker malformation, pachygyria, holoprosencephaly, and anencephaly), gastrointestinal malformations (esophageal, intestinal, or anal atresia in SRP I, II, and III, malrotation in IV), narrow chest, micromelia, and postaxial polydactyly. SRP types II and IV have bifid epiglottis with median cleft lip and palate. SRP IV infants are also found to have hepatic and pancreatic cysts with fibrosis, much like ATD and ARPKD.

### 63.7.4 Hajdu–Cheney Syndrome (MIM 102500)

This autosomal dominant skeletal dysplasia is an acroosteolytic condition with progressive, slow, centrifugal resorption of the distal and middle phalanges of the hands and feet beginning in adolescence. The initial abnormality in affected infants is widening of the sagittal and/or lambdoid sutures. Other craniofacial abnormalities that develop with age are persistently open sutures, wormian bones, elongation of the sella turcica, coarse hair and facies, broad forehead, hypertelorism with downslanting palpebral fissures, broad nasal bridge, and premature loss of teeth. Short stature, osteoporosis, and joint laxity are also observed. Polycystic kidneys similar to ADPKD were noted in approximately 10–14% of affected children, often with concomitant hypertension and CRI (249–251). Other renal anomalies, such

as unilateral multicystic dysplastic kidney, vesicoureteral reflux, and glomerulonephritis have been noted.

### 63.7.5 Campomelia, Cumming Type (MIM 211890)

This autosomal recessive, skeletal dysplasia is characterized by premature stillbirth, cervical hygromas with hydrops fetalis, narrow chest, shortened limbs with bowing of all long bones, especially the tibiae and ulnae, and cloverleaf skull (252–254). Biliary ductal plate malformation and hepatic fibrosis, pancreatic fibrosis, and renal cortical and medullary cysts are seen (254,255). Abnormalities of situs, specifically dextrocardia, left-sided superior vena cava, right-sided aortic arch, total anomalous pulmonary venous return, and polysplenia have been reported in several fetuses with this disorder (252,255,256).

### 63.7.6 Glutaric Acidemia Type II (MIM 231680)

Glutaric acidemia type II, also known as multiple acyl-CoA dehydrogenase deficiency, is an autosomal recessive disorder caused by mutations in *ETFA*, *ETFB*, or *ETFDH*, genes that encode the electron transport flavoprotein (ETF) and ETF ubiquinone oxidoreductase (ETF:QO). ETF is the ultimate electron acceptor in branched-chain amino acid, long-chain fatty acid, and choline metabolism. ETF:QO transfers electrons from ETF to the electron transport chain. Deficiency in either enzyme causes a phenotype that is a combination of fatty acid oxidation disorders and isovaleric acidemia, with metabolic acidosis, hypoketotic hypoglycemia, hepatomegaly, hypotonia, and a “sweaty foot” odor. Malformations such as enlarged anterior fontanel, high forehead, flat nasal bridge, telecanthus, and ear anomalies may be present. Bilaterally enlarged, polycystic kidneys with medullary dysplasia can be seen, especially in patients with more severe disease. Presumptive diagnosis can be made from plasma acylcarnitine and urine organic acid analysis. Fibroblast assay of ETF and ETF:QO activity and molecular genetic testing of *ETFA*, *ETFB*, and *ETFDH* confirm the diagnosis.

### 63.7.7 Carnitine Palmitoyltransferase II Deficiency, Neonatal Lethal Form (MIM 608836)

The carnitine palmitoyltransferase II (CPT II) enzyme catalyzes the reconstitution of long and very-long-chain acylcarnitines to coenzyme A following translocation into the mitochondrion. Patients with CPT II deficiency are consequently unable to metabolize long-chain fatty acids and become energy deficient during periods of fasting. CPT II deficiency can present at any time, but severely affected infants who present in the first few

days of life with lethargy, poor feeding, tachypnea, metabolic acidosis, hepatomegaly, hypothermia, and hypoglycemia have been noted to have enlarged, polycystic kidneys with parenchymal dysplasia. Presumptive diagnosis can be made from free and total carnitine levels, plasma acylcarnitine profile, and urine organic acid analysis. The diagnosis is confirmed by measuring CPT II activity in fibroblasts or molecular testing of the *CPT2* gene.

### 63.7.8 Zellweger Syndrome (MIM 214100)

Also known as cerebrohepatorenal syndrome, Zellweger syndrome is a disorder of peroxisome biogenesis that lies at the severe end of a clinical spectrum that includes neonatal adrenoleukodystrophy and infantile Refsum disease. This group of disorders is genetically heterogeneous. Mutations have been found in 12 different genes, all encoding proteins necessary for normal peroxisome assembly. *PEX1* is the most commonly implicated, and the mode of inheritance for all types is autosomal recessive. Patients present in early infancy with severe hypotonia, hyporeflexia, and poor feeding. Many are initially suspected of having a type of myopathy. Dysmorphic examination shows macrocephaly with an extremely large anterior fontanelle, high forehead, flat facies, hypertelorism with upslanting palpebral fissures, and hepatomegaly. Plain-film X-rays reveal stippling of the patellae and long bone epiphyses. Most patients have brain malformations and suffer from myoclonic or generalized tonic-clonic seizures. A vast majority die before the first birthday; survivors are severely mentally retarded. Polycystic kidneys are present in most patients. Zellweger syndrome can be screened for by measuring plasma very-long-chain fatty acids, which are elevated in this condition. Additional testing may include analysis of plasmalogens in erythrocytes, bile acid intermediates, and measurement of phytanic acid and pristanic acids in plasma. Complementation studies can be performed on fibroblasts to identify which peroxisomal gene is deficient. Molecular diagnostic testing is commercially available for many of the *PEX* genes.

There are other genetic syndromes associated with renal cysts. These syndromes and their mode of inheritance are shown in Table 63-4.

## 63.8 MECHANISMS OF CYSTOGENESIS

How do mutations in the polycystins, fibrocystin, and nephrocystins result in cyst formation? While all the mechanisms are not clear, increasing knowledge of the primary cilia of renal tubular epithelial cells has shed light on some of the mechanisms.

Each epithelial cell of the distal convoluted tubule and collecting duct contains a single primary cilium that is nonmotile, with microtubules arranged in a 9+0 pattern. Once thought to be a vestigial organelle, the primary

cilium is now known to be necessary for sensing extracellular shear stress from perpendicular fluid flow and transducing an increase in intracellular calcium ion concentration (257). Studies have also shown that primary cilia are necessary for maintenance of planar cell polarity

through various cellular signaling pathways (e.g. Wnt signaling), and loss of cilia results in abnormal orientation of cell division and cystogenesis (258).

Polycystin-1, polycystin-2, fibrocystin, and the nephrocystins all localize to the primary cilia of renal epithelial cells, and some at basal bodies, centrosomes, focal adhesions or adherens junctions (Figure 63-12). Likewise, the genes associated with syndromic forms of cystic kidney disease (i.e. Joubert syndrome, BBS, Meckel–Gruber syndrome, etc.) demonstrate similar localization.

Polycystin-1 and polycystin-2 directly interact with one another through their C-terminal coiled-coil domains to form a complex. This complex mediates calcium influx in response to shear stress by sensing the bending of the primary cilium (259,260). The large extracellular domain of polycystin-1 functions as a mechanosensor of urine flow, which triggers calcium influx through polycystin-2 channels. The initial calcium current has been shown to “feed forward” and trigger release of intra-organellar calcium stores via the ryanodine receptor. The polycystin complex is also believed to play a role in regulation of the cell cycle (261). Expression of mutant *PKD1*, blockade with polycystin-1- and polycystin-2-specific antibodies, or other disruptions of this system results in impaired calcium influx, leading to increased cAMP levels, and ultimately, abnormal cell proliferation and cell dedifferentiation (Figure 63-13) (6,78,262). The flow-sensor function of the polycystins in the primary cilium may be a contributing pathway in the pathogenesis

## Polycystin and ADPKD

Autosomal dominant polycystic kidney disease (ADPKD) is due to mutations in one of two genes, PKD1 and PKD2, which code for the linked transmembrane proteins polycystin 1 and polycystin 2, found on the primary cilium present on almost all renal tubular cells (not on the intercalated cells) and collecting ducts. Polycystin 1 is expressed predominantly in the distal convoluted tubule and collecting ducts, while polycystin 2 is expressed predominantly in the distal convoluted tubule and loop of Henle.

FIGURE 63-13

of cyst formation in kidneys with obstructed flow, such as ureteropelvic or ureterovesicular junction obstruction.

Nephrocystin-1 and fibrocystin have also been found at the primary cilium in association with the polycystin protein complex and are also thought to participate in the same mechanotransduction pathway (125,126,174,263,264).

The Wnt signaling pathway is an integral part of the pathogenic process of renal cyst formation (Figure 63-14). Under normal circumstances, cilia respond to fluid flow, and the calcium signaling cascade is initiated. As a result, several proteins, including nephrocystin-2/inversin and the BBS proteins, are activated and shift the Wnt pathway from its canonical to non-canonical mode (185,265,266). As a result of this shift,  $\beta$ -catenin, which normally acts as a transcriptional activator, is degraded by proteasomes, and normal planar cell polarity is maintained. When calcium signaling or ciliary proteins are defective, the canonical Wnt pathway predominates, and  $\beta$ -catenin is able to translocate into the nucleus where it forms an active transcription factor complex with the T-cell-specific transcription

factor/lymphoid enhancer binding factor (TCF/LEF) and promotes the expression of fetal genes to induce cell proliferation and differentiation, ultimately resulting in cyst formation.

Polycystin-1, polycystin-2, and nephrocystin-1 also aggregate into a complex that co-localizes in vivo with  $\alpha 2 \beta 1$  integrin and co-immunoprecipitate with multiple focal adhesion adaptor proteins, most notably focal adhesion kinase, c-src, and p130cas (170,171). In response to ligand binding, the polycystin complex activates c-Jun kinase and mitogen-associated protein kinase via focal adhesion adaptor proteins, leading to phosphorylation and activation of the c-Jun protein, a member of the AP-1 transcription factor family. Phosphorylated c-Jun dimerizes with ATF, another member of the AP-1 family, to create an active transcription factor that drives the expression of genes responsible for differentiation and reduction of proliferation in developing renal tubular epithelium (267) (Figure 63-15A). Inactivation of AP-1 transcription factor-mediated gene expression by abrogation of polycystin-1 and/or 2 signaling results in inability to downregulate proliferation and fetal gene

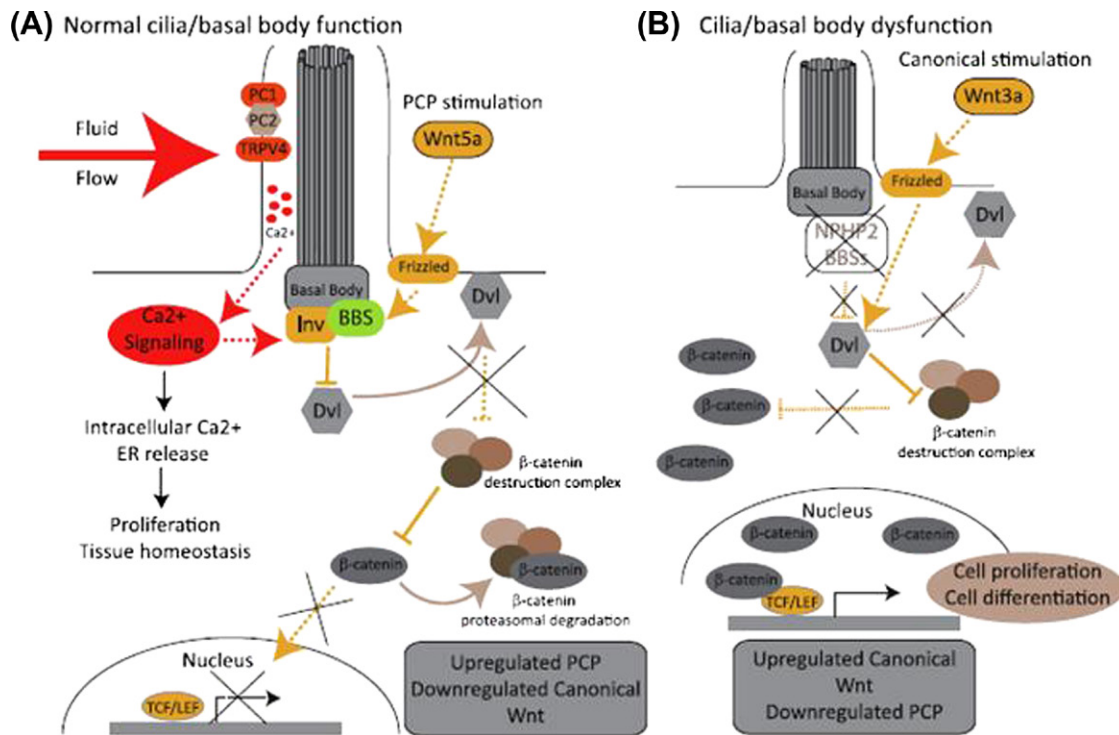

FIGURE 63-14 Katsanis, N., et al., *Pediatric Nephrology* 2010, 6, Fig 2.

FIGURE 63-15

expression, leading to conditions that foster cyst formation (268,269) (Figure 63-15B,C). The exact role of nephrocystin-1 at the focal adhesion complex is not well defined, although its SH3 domain may be responsible for recruiting c-src and p130cas to the polycystin protein complex.

The function of the other nephronophthisis genes, especially in relation to cerebral and ocular development, is less well defined. While nephrocystin-3 and nephrocystin-4 have been found to associate with nephrocystin-1, it is not yet known which signaling pathways they participate in and how. Inversin interacts with the anaphase-promoting complex via its two

“destruction-box” domains, possibly linking environmental stimuli sensed by primary cilia to the centrosome and regulation of cell division (154). Finally, inversin is involved in early embryogenesis as one of the determinants of left–right axis patterning, perhaps through its interaction with mechanosensory cilia (270,271).

Much progress has been made in our understanding of renal cystogenesis. Although questions remain to be answered, our increasing knowledge of the genetic and molecular basis of cystic kidney diseases will enhance insight into the pathogenesis, clinical consequences, and ultimately, the treatment of these disorders.

### Biographies

**Angela Sun, MD**, is a native of Irvine, California. She attended Washington University in Saint Louis where she majored in Biology and French. She earned her medical degree from Saint Louis University and then completed her internship and residency in pediatrics at the University of California, Irvine. She finished her fellowships in clinical genetics and medical biochemical genetics at the UCLA Intercampus Medical Genetics Training Program.

**Raymond Y Wang** is a member of the Pediatric Subspecialty Faculty in the Division of Metabolic Disorders at the CHOC Children's Hospital in Orange, California. He attended medical school at the University of California-Los Angeles and completed his residency in pediatrics and medical genetics at the University of California-Los Angeles/Cedars-Sinai Medical Center. He went on to complete a fellowship in Clinical Biochemical Genetics in the UCLA Intercampus Medical Genetics Training Program. Among his research interests are studying the clinical outcomes of infants prospectively identified via newborn screening to have inborn errors of metabolism. One such disorder currently under investigation is short-chain acyl-CoA dehydrogenase deficiency. Another initiative he has been actively involved with is delineating potential strategies for follow-up evaluations and treatment of lysosomal storage disorders identified via newborn screening.

**Dechu P Puliyaanda, MD**, completed her medical schooling in India and finished her pediatric residency at the Rush Presbyterian St. Luke's Medical Center, Chicago, Illinois. She then completed a 3 year fellowship in pediatric nephrology and transplantation at the Children's Hospital, Harvard Medical School, Boston. She was recruited as a faculty at the Cedars-Sinai Medical Center, Los Angeles, California in 2000. She also holds a faculty position at the UCLA David Geffen School of Medicine.

This article is a revision of the previous edition article by Hannu Jalanko, Helena Kääriäinen, Reijo Norio, volume 2, pp 1503–1512, © 2007, Elsevier Ltd.

### 64.1 INTRODUCTION

Nephrotic syndrome (NS) is a clinical diagnosis characterized by heavy proteinuria, hypoproteinemia, and edema. It occurs in various forms of acquired renal diseases, such as glomerulonephritides and membranous nephropathy, or may be part of systemic diseases, such as vasculitis, lupus erythematosus, and amyloidosis. NS may also be caused by infections, such as human immunodeficiency virus (HIV), maternal syphilis, toxoplasmosis, and malaria. Toxic agents such as mercury, insect stings, or maternal steroid–chlorpheniramine treatment are also associated with NS.

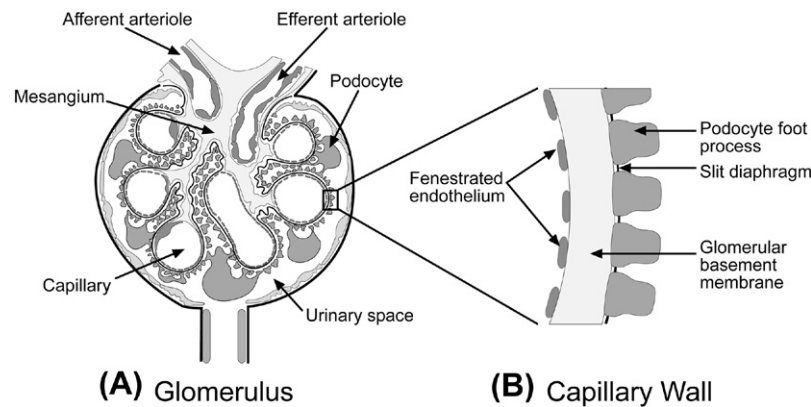

The most common variety of primary NS in children is steroid-sensitive nephrotic syndrome (SSNS). Approximately 80% of all children with NS respond to prednisone therapy and renal biopsy indicates minimal histological changes (MCNS) in 80% and focal segmental glomerulosclerosis (FSGS) in 20% (1). Twenty percent of NS in children show steroid resistance (SRNS). Seventy-five percent of these patients exhibit renal histological features of FSGS, and 20% demonstrate MCNS. Overall, MCNS and FSGS account for over 90% and 5% of NS in the pediatric age group, respectively. FSGS is especially common in African-Americans, and the incidence of FSGS in children has increased. In adults the situation is different, and FSGS is the most common type of NS. Typically FSGS manifests as NS but progresses to renal failure within months or years. FSGS is a significant cause of end-stage renal disease (ESRD), comprising up to 5% of adults and 20% of children with ESRD. The pathophysiology of SSNS and SRNS is mostly unknown, but T-lymphocyte dysfunction has been regarded as the basic event. In addition, circulating permeability factors have been suggested as the etiology for SSNS and SRNS, but their presence has not been verified (2).

During the past decade gene defects both in autosomal recessive and dominant forms of SRNS have been identified. To date, approximately 10–20% of sporadic and 30–40% of familial cases of SRNS are associated with a gene defect (3,4). These new genes include nephrin (*NPHS1*), podocin (*NPHS2*), Wilms' tumor factor 1 (*WT1*), phospholipase Ce1 (*PLCE1*), laminin  $\beta$ 2 (*LAMB2*), transient receptor potential C6 ion channel (*TRPC6*), CD2-associated protein (*CD2AP*), alpha-actinin-4 (*ACTN4*), and inverted formin 2 (*INF2*) genes. It is to be expected that more pathogenetic gene defects will be identified in the future. The known gene disorders cover about two-thirds of NS in early childhood and less than 20% of the cases with late-onset of NS.

Recent discoveries indicate that NS caused by a particular gene defect can manifest at various ages. Thus, the traditional classification of NS into congenital (CNS; onset <3 months of age), infantile (INS, onset at 4–12 months) and late-onset (>12 months) is not valid anymore. However, the terms are still useful in clinical practice. Similarly, the histological features of the kidney overlap in the different genetic and nongenetic entities, so that the microscopic findings do not provide the basis of the classification or tell the specific diagnosis. The clinical renal and extrarenal manifestations, kidney histology, and the age at onset, however, give a clue to the possible gene defect involved. This review focuses first on the major genetic entities and then deals with the diagnostics and management of NS patients.

### 64.2 GLOMERULAR FILTRATION BARRIER

In the kidney, filtration of plasma takes place in the glomerular capillary tuft surrounded by the urinary

**FIGURE 64-1** The structure of kidney glomerulus (A) and glomerular capillary wall (B). Primary urine is formed in the glomerulus by passing of plasma water and small-molecular-weight molecules through the capillary wall (glomerular filtration barrier) into the urinary space. In nephrosis plasma proteins also leak through this barrier, which is composed of three layers: fenestrated endothelium, glomerular basement membrane, and podocyte foot processes. These are connected by the slit diaphragm, which is important for the proper function of the filtration barrier. (Figure 64-1A is modified from the original figure by Professor Wilhelm Kriz.)

space and Bowman's capsule (Figure 64-1). The ultrafiltration barrier in the capillary wall comprises three layers: fenestrated endothelium, glomerular basement membrane (GBM), and epithelial cell (podocyte) layer with distal foot processes and interposed slit diaphragms (SDs). The barrier is a highly sophisticated size- and charge-selective molecular sieve, and normally only water, electrolytes, and small plasma solutes pass through this barrier (5–7). The flow of glomerular filtrate follows the extracellular route, passing across the GBM and then across SDs, which bridge adjacent foot processes just above the GBM.

Studies performed during the past decade have clearly indicated that podocytes and the SD are essential in restricting the passage of plasma proteins into urine (8,9). The precise molecular structure of SD is still unresolved, but podocyte proteins nephrin, Nephrin, Nephrin, Fat1, Fat2, cadherins, and dendrin seem to be its essential components (10,11) (Figure 64-2). Nephrin and Nephrin are believed to associate with each other extracellularly and they form the backbone of the SD (12–14). The SD proteins interact with the adapter proteins podocin, CD2AP, ZO-1, CASK, IQGAP1, MAG I, catenins, and spectrins that are located in the cytosolic part of the podocyte foot process (Figure 64-2) (15–19). The adapter proteins connect the SD with the actin cytoskeleton of the podocyte foot process and take part in the signal transduction from the SD into podocyte (9,17).

The actin network and the interacting proteins, such as  $\alpha$ -actinin-4, are critical for the maintenance of the complex structure of the podocyte foot process (20). Practically all forms of NS lead to podocyte injury with foot process flattening (effacement) and distortion of normal SD structure (21). This is believed to reflect a defective interplay of the SD components, adapter proteins and the actin network itself. The discovery of NS caused by mutations in the GBM components (laminin- $\beta$ 2) highlights the importance of the GBM, podocyte foot

**FIGURE 64-2** A hypothetical model of the podocyte foot process and slit diaphragm. Nephrin and Nephrin possibly form the backbone of the extracellular part of the slit diaphragm. Other molecules, such as Fat 1 and dendrin have also been localized to this structure. Adapter proteins, such as podocin, CD2AP, ZO-1, CASK, IQGAP1, MAG1, Nck, catenins, and spectrins are intracellular molecules that interact with nephrin and Nephrin and connect the slit diaphragm to actin cytoskeleton of the podocyte foot process. The calcium-channel TRCP6 is also believed to interact with the slit diaphragm complex.

processes, and the SD in maintaining a properly functioning glomerular filtration barrier (22).

### 64.3 NEPHRIN GENE (*NPHS1*) MUTATIONS

Nephrin is a transmembrane adhesion protein of the immunoglobulin family. The extracellular part of nephrin contains eight immunoglobulin-like motifs and one type III fibronectin domain (8). The intracellular domain has nine tyrosine residues, some of which become phosphorylated during ligand binding. Nephrin is synthesized by glomerular podocytes and localized at the SD area between the podocyte foot processes (8). Nephrin is encoded by the *NPHS1* gene, located on chromosome 19q13.1. It consists of 29 exons and has a size of

26kb. Mutations in *NPHS1* causes congenital nephrotic syndrome of the Finnish type (CNF, *NPHS1*), which is a prototype of CNS.

### 64.3.1 Congenital Nephrotic Syndrome of the Finnish Type (CNF, *NPHS1*)

CNF (OMIM 602716) is an autosomal recessive disease first described in Finland. The incidence in Finland is 1 in 8000 live births. CNF has been reported from all over the world in different ethnic groups (23–25). A very high incidence of CNF has been observed among the Old Order Mennonites in Lancaster County, Pennsylvania. Exon sequencing analyses of Finnish patients revealed the presence of two truncating mutations in 94% of *NPHS1* chromosomes (Fin-major and Fin-minor) (8,26). The uniform mutation pattern seen in the Finnish population can be explained by the founder effect (27). Most non-Finns have individual mutations and to date roughly 150 different mutations have been described, spanning the whole gene. Mutations in the promoter area have also been found. Most missense mutations in *NPHS1* lead to the misfolding of nephrin molecule and a defective intracellular nephrin transport in the podocyte (28). In four recent reports of *NPHS1* mutations in the European and worldwide cohorts of CNS, nephrin gene mutations accounted from 39 to 80% of the cases. (29–32). Overall, about half of CNS seems to be caused by *NPHS1* mutations.

The majority of typical CNF children are born prematurely with a birth weight ranging between 1500 and 3500g (33). The index of placental weight/birth weight (ISP) is over 25% in practically all newborns. The reason for this is not known. Proteinuria begins in utero and is thus detectable in the first urine sample tested. Heavy protein losses result in hypogammaglobulinemia (34) as well as low antithrombin III levels and increased risk for thrombotic complications (26). Hyperlipidemia is also present, as in other nephroses. Infants with CNF do not have any major extrarenal malformations. Minor functional disorders in the central nervous system, cardiac hypertrophy, and muscular hypotonia, however, are common during the nephrotic stage.

No single histological finding is pathognomonic for CNF. In the early stage, proliferation of mesangial cells and increase of mesangial matrix are seen (35). Dilations of the proximal and distal tubules are the most characteristic findings. Their amount varies greatly, from an occasional dilation to a universal dispersion throughout the renal cortex. In the interstitium, fibrosis and inflammatory infiltrates increase with age. In electron microscopy, the principal finding is the fusion and effacement of podocyte foot processes, seen in many nephrotic kidney diseases (21). The Fin-major and Fin-minor mutations of the *NPHS1* lead to a complete absence of nephrin in the kidney glomerulus (33). These kidneys also lack the filamentous image of podocyte SDs as studied by electron

microscopy, indicating that the absence of nephrin leads to distortion of the SD and the leakage of plasma proteins into urine through the “empty” podocyte pores (11).

### 64.3.2 Childhood-Onset NS

Mutations in *NPHS1* are quite rare in cases manifesting after the first weeks of life (29,30). However, Philippe et al. (36) analyzed DNA from 160 patients in 142 families with NS presenting after 3 months of age. Putative disease-causing nephrin mutations were found in 10 families, with the age of onset ranging from 6 months to 8 years. Biopsy findings showed minimal changes in six of the patients and FSGS in three patients. ESRD had developed in five patients at the age of 6–25 years. Mutations were classified as severe or mild and the presence of at least one mild mutation in these patients likely explains the later onset and milder course of disease. Santin et al. (30) report a similar study of 97 FSGS patients from 89 unrelated families. Disease-causing *NPHS1* defects were observed in seven sporadic and five familial cases. Three of the individuals were 1 year of age or older, and one was 27 years old at the time of disease onset. The results broaden the spectrum of renal disease related to nephrin gene mutations.

## 64.4 PODOCIN GENE (*NPHS2*) MUTATIONS

Podocin is a hairpin-like protein of the stomatin-family and is exclusively expressed in podocytes, where it is an important component of the lipid rafts of the filtration slit (Figure 64-2) (37). Podocin plays a major role in the structural integrity and function of the SD (38). This protein is encoded by the *NPHS2* gene composed of eight exons and located on chromosome 1q25-q31. Genetic defects in *NPHS2* (OMIM 604766) can lead to NS starting at any age.

### 64.4.1 Congenital and Childhood SRNS

Koziell and colleagues (24) first reported that two of five CNS patients lacking *NPHS1* mutations had homozygous *NPHS2* mutations. Schultheiss and coworkers (39) reported *NPHS2* mutations in 11 CNS patients with FSGS histology in half the kidney biopsies. Half the patients developed ESRD at a median age of 6 years. In accordance with these two studies, 14 homozygous or compound heterozygous mutations were found in *NPHS2* in a cohort of 22 patients with CNS (40). Recently, Hinkes et al. (29) performed an analysis of *NPHS1*, *NPHS2*, *WT1* and *LAMB2* genes in a large European cohort of 89 children from 80 families with NS manifesting in the first year of life. They detected disease-causing mutations in 66% of the families. Interestingly, both *NPHS1* and *NPHS2* mutations accounted for an equal number (39.1%) of CNS cases. In patients with the infantile form

of NS, NPHS2 mutations were still responsible for 35% of cases, while NPHS1 mutations were not detected.

Besides CNS, NPHS2 mutations have been found in families with an autosomal-recessive form of SRNS manifesting later in life (41–44). In one study, NPHS2 mutation analysis was performed in 338 patients from 272 families with SRNS. The mutation detection rate in NPHS2 was 43% for the familial cases. NS in these patients manifested at the mean age of 3.4 years. In another study, mutation analysis of NPHS2 was performed on 190 patients with SRNS from 165 families (40). Homozygous or compound heterozygous mutations in NPHS2 were detected for 56 of 190 patients (29%). Twenty-seven of these 56 patients represented familial cases. The age of the patients with NPHS2 mutations varied from birth to 24 years, with a median of 3.5 years. In a 2008 study, a worldwide cohort of 430 patients from 404 different families with SRNS was screened for NPHS2 mutations (45). Recessive podocin mutations were present in 18.1% (73/404) of families. Patients with these mutations manifested symptoms at a significantly earlier age (mean onset < 1.75 years) than any other patient group.

To date, more than 100 different NPHS2 mutations have been identified in patients with SRNS. As a rule, they appear in both alleles (homozygous or compound heterozygous) in accordance with autosomal recessive inheritance. The mutations are distributed throughout the entire gene. Most mutations cause a severe disease with an early onset and development of ESRD within a few years. The molecular basis for this is that many of the disease-causing mutations in podocin seem to disrupt nephrin trafficking to the plasma membrane of podocytes, which severely interferes with the SD structure and function (46,47). The podocin gene mutations do not cause any extrarenal defects.

### 64.4.2 Late-Onset SRNS

NPHS2 mutations have also been described in familial cases of SRNS with adolescent or adult onset. Many of these late-onset cases are compound heterozygotes, with one allele harboring a R229Q mutation (44,48). The R229Q variant is present in the heterozygous state in approximately 4% of Western populations. It encodes a defective podocin protein with low affinity for binding to nephrin. Recently, Machuca et al. (49) sequenced the podocin gene in 546 patients from 455 families SRNS. Thirty-six patients from 27 families were compound heterozygotes for the p.R229Q variant and one pathogenic mutation. These patients had significantly later onset of NS than patients with two pathogenic mutations. Among 119 patients diagnosed after 18 years of age, 18 patients were found to have one pathogenic mutation and p.R229Q, but none had two pathogenic mutations. In the study by Santin et al. (50), mutation analysis was performed in 148 unrelated Spanish patients with SRNS.

Homozygous or compound heterozygous NPHS2 pathogenic mutations were identified in 7 of the 92 pediatric patients and in none of the adult FSGS patients. On the other hand, four of the 47 adult patients were compound heterozygotes for p.R229Q and one pathogenic mutation (mostly p.A284V).

Studies show that compound heterozygosity for p.R229Q is associated with adult-onset SRNS. Screening for the pR229Q variant is recommended in these patients, along with further NPHS2 mutation analysis in those carrying the variant. The role of p.R229Q homozygosity in SRNS is less well defined. It seems to increase the risk for SRNS although the magnitude of this effect remains unknown. NPHS2 mutations are the most common podocyte gene defects. Yet, mutations are found in a minority of SRNS patients. In a 2007 study, no homozygotes or compound heterozygotes were observed in 377 biopsy-confirmed late-onset FSGS (51). Similarly, no NPHS2 mutations were observed in 39 Brazilian patients with adult-onset FSGS (52) or in 18 African–American children with SRNS (53). He et al. (54) screened NPHS2 mutations in 87 adult patients with idiopathic FSGS (15 steroid-sensitive, 63 steroid-resistant, and nine familial cases) and found compound heterozygous mutations only in one patient and no homozygous mutations.

## 64.5 WILMS TUMOR SUPPRESSOR GENE (*WT1*) MUTATIONS

WT1 encodes for a nuclear WT1 protein, which is a transcription factor of the zinc finger family. WT1 plays a crucial role in the embryonic development of the kidney and genitalia. In the mature kidney, WT1 is expressed in podocytes and epithelial cells of the Bowman's capsule. WT1 contains 10 exons, the first six of which encode a proline/glutamine-rich transcriptional regulatory region. Exons 7–10 encode the four zinc fingers of the DNA-binding domain. Up to 24 different isoforms of WT1 may result from the combination of alternative translations sites, alternative RNA splicing, and RNA editing. The biological role of all these isoforms is not known (1,3).

A variety of WT1 mutations, which either affect development or induce tumor formation, have been identified (Chapter 59). Developmental defects include the WAGR syndrome, Denys–Drash syndrome (DDS), and Frasier syndrome (FS) (Chapter 66). Mutations in WT1 can also cause an isolated kidney disease with NS. The histopathological diagnosis in these cases may be diffuse mesangial sclerosis (DMS) or FSGS (55).

### 64.5.1 Denys–Drash Syndrome

DDS (OMIM 194080) classically meant a combination of NS showing a histopathologic picture of DMS, male pseudohermaphroditism, and Wilms tumor. Male pseudohermaphroditism in most published cases refers to an

XY karyotype, some testicular tissue elsewhere than in the scrotum, variable degrees of ambiguous genitalia, such as hypospadias and cryptorchidism in children appearing like boys, or hypertrophy of the clitoris in phenotypic girls. Some cases with an XX karyotype and female phenotype have been reported. Three clinical categories of DDS have been noted: genotypic males with all three abnormalities, genotypic males with nephropathy and ambiguous external and/or internal genitalia only, and genotypic females with nephropathy and Wilms' tumor only (1,3).

DDS is caused by heterozygous mutations in *WT1*. More than 60 germ line mutations (both familial and de novo) have been described in DDS patients. Most are missense mutations within exon 8 and 9, coding for zinc finger domains 2 and 3, which lead to alteration in the DNA-binding capacity of *WT1*. It is believed that the mutant protein actively suppresses the normal allele, which explains the more severe phenotype seen in DDS compared with children with complete deletion of one *WT1* allele. In most patients, the nuclear expression of *WT1* is absent or reduced in podocytes. The podocyte function is affected and, at the molecular level, upregulation of *PAX2* and downregulation of *nephrin* have been reported (56). In addition, the expression of growth factors that regulate glomerular capillary development is affected in DDS (57). Missense mutations can occur with or without *WT*. *WT1* analysis is important in young patients with NS for early detection and tumor prophylaxis. The nephropathy is usually discovered at the age of a few months, sometimes at birth. To avoid the development of Wilms' tumor, bilateral nephrectomy at the onset of terminal renal failure is recommended. Removal of native kidneys has been suggested for all patients with nephropathy caused by *WT1* mutations (58).

### 64.5.2 Frasier Syndrome

FS (OMIM 136680) is characterized by the association of male pseudohermaphroditism and glomerulopathy (1,3). There is complete male to female gender reversal in 46,XY patients. FS is associated with gonadoblastomas, but not with Wilms' tumor. Proteinuria is detected in childhood, usually between 2 and 6 years of age, and kidney biopsy reveals FSGS. The renal disease does not respond to medical therapy, but it has a slower progressive course to renal failure than DDS.

FS is caused by point mutations in intron 9 in *WT1*, which interferes with the recognition of the second splice donor site of *WT1*. This results in the loss of the lysine-threonine-serine (KTS)-containing isoforms of *WT1*. How this change in the relative expression of +KTS and -KTS isoforms results in the severe developmental defects in FS is not completely understood (1). In addition, mutations in exon 9 that do not alter the +KTS isoform expression have been reported in FS patients. On the other hand, typical FS mutations have

been observed in DDS patients. Based on this overlap, both diseases should be considered as part of a spectrum of *WT1* gene mutations, rather than as separate entities. Recently, Chernin et al. (59) followed 19 patients with mutations in intron 9 splice site (KTS mutations), 27 patients with missense mutations, and six patients with other mutations. Totally 24 different *WT1* mutations were detected. Sixteen of the 19 patients with KTS mutations were females. The results showed that KTS mutations cause isolated NS with the absence of Wilms tumor in 46,XX females. On the other hand, these mutations cause FS with gonadoblastoma risk in 46,XY phenotypic females.

### 64.5.3 Isolated Kidney Disease

Originally, three studies reported *WT1* mutations in patients with isolated DMS. Since then, the incidence of *WT1* mutations has been evaluated in sporadic cases of SRNS and SSNS (60). Mutations in exons 6–9 of *WT1* were identified in 8 of the 115 SRNS patients (7%). In two females, mutations in exon 9 consistent with the diagnosis of DDS were identified; one of them had Wilms tumor. In three male and three female patients, splice site mutations in exon 9 consistent with the diagnosis of FS were found. Two of the male patients presented with urinary or genital malformations, one of them with sexual reversal and bilateral gonadoblastoma. All three female patients presented with isolated FSGS. No mutations were found in 110 patients with sporadic SSNS. In a recent study, *WT1* mutations were observed in 5 of 110 patients (4.5%) with SRNS. All patients were less than 5 years of age at onset of NS (61). Interestingly, Mucha et al. (62) screened a worldwide cohort of 164 cases of sporadic SRNS, all of whom were 18 years or less at the onset of NS. All 10 exons of *WT1* were analyzed and 15 patients exhibited seven different mutations exclusively in exons 8 and 9 of *WT1*, suggesting that screening of *WT1* exons 8 and 9 in patients with sporadic SRNS is sufficient to detect pathogenic mutations.

## 64.6 PHOSPHOLIPASE C $\epsilon$ 1 GENE (*PLCE1*) MUTATIONS

PLC $\epsilon$ 1 belongs to the phospholipase family of proteins that catalyze hydrolysis of phosphoinositides, generating messengers such as IP<sub>3</sub> and DAG, which are involved in a wide spectrum of intracellular functions (63). Phospholipase C isoenzymes can be activated by G-protein-coupled receptors. The main action of IP<sub>3</sub> is the stimulation of calcium release from intracellular storage pools, which could be involved in cytoskeletal reorganization and modulate the function of other signal transduction cascades. PLC $\epsilon$ 1 was found to associate with IQGAP1, a protein that has been shown to interact with *nephrin*. A link between PLC $\epsilon$ 1 and RasMAP kinase signaling pathway has also been suggested (64).

The precise function of PLC $\epsilon$ 1 in podocytes, however, remains to be clarified.

In 2006, Hinkes et al. (65) identified mutations in *PLCE1* as causing early-onset NS (OMIM 610725). The age at onset in the 12 patients varied from 2 months to 4 years and the age at ESRD from 5 to over 13 years. No extrarenal manifestations were observed. Kidney histology showed DMS in most patients. Two siblings with a missense mutation had characteristics of FSGS. Two other affected individuals responded to immunosuppressive therapy, making this the first report of a molecular cause of NS that may resolve after therapy. The study showed that PLC $\epsilon$ 1 is expressed in developing and mature podocytes and the DMS histology possibly represents developmental arrest.

In a subsequent study, Gbadegesin et al. identified 40 children from 35 families with idiopathic DMS from a worldwide cohort of 1368 children with NS (66). The age of onset varied from 1 month to 6 years. Truncating mutations in *PLCE1* were detected in 28.6% (10/35) of the families and, interestingly, WT1 mutations in only 8.5% (3/35). Except in one family, all the mutations detected were homozygous loss-of-function mutations. One child had two compound heterozygous mutations. Fourteen children were placed on corticosteroid or cyclosporine therapy and no one responded. Age at ESRD varied from 8 months to 5 years.

So far, the results show that *PLCE1* is a major gene causing isolated DMS and subjects with this type of histological lesion should be screened for *PLCE1* mutations. The mutations may also lead to FSG with a relatively late-onset of proteinuria. *PLCE1* mutations, however, remain an infrequent cause of FSGS. A Dutch study did not find *PLCE1* mutations in 19 cases of childhood-onset FSGS (67) nor were mutations in this gene found in 69 families (median age of onset 26 years) with idiopathic or hereditary FSGS (68). Similarly, *PLCE1* mutations were not found in 125 Spanish patients with SRNS (ranging from congenital to adult onset) (61). Interestingly, some individuals with *PLCE1* mutations may also remain asymptomatic, implying that there may be modifier genes that interact with *PLCE1* to cause DMS/FSGS.

### 64.7 LAMININ- $\beta$ 2 GENE (*LAMB2*) MUTATIONS

Laminin  $\beta$ 2 is one of the laminin chains and component of laminin-521, which has an  $\alpha$ 5: $\beta$ 2: $\gamma$ 1 conformation. Laminin-521 is specifically expressed in the GBM and at some other sites such as intraocular muscles and neuromuscular synapses. Laminin is able to polymerize in a regular manner and has a critical role in maintaining the structural properties of the GBM. Laminin-521 also interacts with its receptor integrin  $\alpha$ 3 $\beta$ 1, which links the GBM to the actin cytoskeleton of the podocyte (22).

In 2004, Zenker et al. (69,70) reported that mutations in the *LAMB2* gene, encoding the laminin  $\beta$ 2 chain,

are associated with Pierson syndrome. This syndrome (OMIM 609049) is a rare autosomal recessive disorder characterized by early-onset NS with variable ocular and neurologic defects. The typical ophthalmic sign is a fixed narrowing of pupils (microcoria), which is due to a defect of the dilator pupillae.

After the original observation, milder variants of the syndrome have been reported with less prominent extrarenal abnormalities (71). Recently, Matejas et al. reviewed the findings in a total of 51 patients from 39 families with *LAMB2* mutations (72). The majority (71%) of the mutations was truncating and was evenly distributed along the *LAMB2* gene. The rest (29%) were missense mutations causing amino acid changes in the N-terminal region of laminin  $\beta$ 2, which is the critical area for interacting with  $\alpha$  and  $\gamma$  chains of neighboring laminin. The age of the patients at diagnosis was mostly less than 3 months, and was over 1 year in only four patients. The age at onset of ESRD was mainly under 1 year (from 1 week to 16 years). Renal biopsy showed DMS histology in 73%, FSGS in 14% and minimal changes in 8% of the patients. Neurodevelopmental deficits were observed in 82% of the patients and all but two patients had some ocular abnormalities. Among patients with isolated NS, *LAMB2* mutations are apparently rare. They were observed in only 2.5% (2/80) of the European patients with congenital or infantile NS (29). Similarly, no *LAMB2* mutations were observed in 33 patients with SRNS and FSGS histology, and there was ocular involvement in 8 patients (73).

### 64.8 TRANSIENT RECEPTOR POTENTIAL C6 ION CHANNEL GENE (*TRPC6*) MUTATIONS

TRPC6 is a receptor-operated cation channel that contributes to changes in the cytosolic free  $\text{Ca}^{2+}$  concentration. TRPC6 is expressed in the podocyte and clustered in the podocin–nephrin–lipid complex. It has been speculated that TRPC6 could be involved in monitoring the integrity of the SD (74). The alteration of TRPC6 function may impair the cytoskeletal adaptive response of podocytes to injury, eventually leading to progressive damage. Studies suggest that nephrin binds to phosphorylated TRPC6 via its cytoplasmic domain, competitively inhibiting TRPC6 expression and activation (75).

In 2005, two groups independently reported that the *TRPC6* gene is mutated in a subset of patients with the autosomal dominant form of FSGS (76,77). A missense mutation in *TRPC6* was reported to be a cause of familial FSGS in a large New Zealand family with FSGS. Subsequently, other families with different *TRPC6* mutations have been reported in both adults and children (78,79). The few published studies, to date, suggest that *TRPC6* mutations account for 3–7% of cases with familial adult-onset FSGS. The affected individuals typically present with high-grade proteinuria. The incomplete penetrance

of TRPC6 mutations to some extent limits its diagnostic value.

### 64.9 CD2-ASSOCIATED PROTEIN GENE (CD2AP) MUTATIONS

CD2-associated protein (CD2AP) is an adapter protein, which interacts with T-cell adhesion protein CD2 and is expressed in lymphoid and epithelial cells. In the kidney, CD2AP localizes to the SD of the podocyte where it links podocin and nephrin to the phosphoinositide 3-OH kinase to form a signaling complex. CD2AP-deficient mice develop severe proteinuria and renal dysfunction shortly after birth. Heterozygous mice develop an FSGS-like lesion around the age of 9 months (80).

The role of CD2AP in human FSGS is still being elucidated, but individuals with homozygous mutations in CD2AP have been reported to present with early-onset FSGS (OMIM 607832). A homozygous mutation (p.R612X) was identified in an infant who presented NS and severe glomerular sclerosis on renal biopsy. The truncated protein displayed a dramatic reduction in actin-binding efficiency in vitro (81). Homozygous mutations of CD2AP, however, are rare and in two studies no CD2AP mutations were detected in adult or pediatric patients with SRNS (61,82).

A heterozygous mutation in the *CD2AP* gene has been reported to be a predisposing factor toward developing a late-onset FSGS. Five different CD2AP heterozygous mutations have been identified in pediatric and adult FSGS patients (80–82), associated with reduced expression of CD2AP and downregulation of CD2AP, nephrin, and podocin expression on kidney biopsies. However, heterozygous CD2AP mutations have been found in unaffected individuals and the causal link between heterozygous CD2AP mutations and FSGS is not yet clear.

### 64.10 ALPHA-ACTININ-4 GENE (ACTN4) MUTATIONS

Alpha-actinin-4 is an actin filament cross-linking protein important for the integrity of the cytoskeleton in podocyte foot processes. While ACTN4 is highly expressed in several tissues, human disorders manifest only in the kidney. Transgenic ACTN4 mice develop a severe glomerular disease (83). Podocyte cell lines derived from these mice show less adherence to collagen IV and laminin, which are important components of the GBM (84).

Mutations in ACTN4 are associated with an autosomal dominant form of familial FSGS (OMIM 603278) (85). The mutated ACTN4 proteins showed higher binding affinity to F-actin, which may change the mechanical characteristics of the podocyte. Only a few ACTN4 missense mutations have been described (85,86). ACTN4 mutations were recently found in 4% of familial FSGS cases. On the other hand, no ACTN4 mutations were observed in 125 Spanish patients with SRNS (61) or in

42 pediatric patients with SRNS (82), indicating that ACTN4 mutations are rare in SRNS. Most reported patients show a mild to moderate degree of proteinuria during adolescence or later, and some patients gradually progress to ESRD. In contrast, Choi et al. (87) recently reported a familial case of FSGS in which two affected siblings showed rapidly progressing NS in early childhood. Renal pathological findings were of an FSGS collapsing variant.

### 64.11 NS CAUSED BY INVERTED FORMIN 2 GENE (INF2) MUTATIONS

INF2 is a member of formins that accelerate cytoplasmic filament nucleation and elongation (88). Formins are widely expressed proteins governing several dynamic events that require remodeling of the actin cytoskeleton such as cell polarity, morphogenesis and cytokinesis. INF2 has the unique ability to accelerate both actin polymerization and depolymerization (89). The regulatory mechanisms controlling INF2 and its cellular function are not well known. INF2 is a widely expressed protein with high expression in the kidney, including glomerular podocytes.

In 2010, Brown et al. (90) identified a locus for autosomal dominant FSGS on a region of chromosome 14q. By sequencing multiple genes in this region, they detected nine independent nonconservative missense *INF2* mutations in a total of 72 individuals from 11 families coming from United States, Canada and Mexico. Patients with INF2 mutations presented in adolescence or adulthood (age range 11–67 years), typically with moderate or nephrotic range proteinuria, but not with NS. The disease was progressive, often leading to ESRD (age range 13–67 years). All mutations altered highly conserved amino acid residues in the diaphanous inhibitory domain of the INF2 protein. These observations underscore the importance of fine regulation of actin polymerization in podocyte function.

A subsequent study by Boyer et al. (91) determined the prevalence of INF2 mutations in a cohort of 54 families (78 patients) with proteinuric disorder of apparent autosomal dominant inheritance. Seven missense mutations were found in nine families (28 patients), which translates to a detection rate of 16.7%. Median age at onset of proteinuria was 27 years and NS was noted in four patients. Median age at ESRD was 36 years (range 20–70 years). Significant intrafamilial phenotypic variability was evident with a wide range of age at presentation and ESRD. An additional familial case of FSGS associated with INF2 mutations was described (92). In this family, two siblings and their father had a heterozygous pE220K mutation. This mutation manifested in these three individuals as incidentally detected proteinuria without overt NS, but at different ages, 7, 9, and 30 years, respectively. Renal biopsy showed FSGS.

### 64.12 OTHER GENETIC FORMS OF NS

In the nail-patella syndrome, NS occurs in a minority of patients and is accompanied by changes in the expression of the GBM components and some podocyte proteins. This syndrome is caused by mutations in the *LMX1B* gene, which codes for a transcription factor strongly expressed in podocytes (93). The link between *LMX1B* mutations and the GBM alterations is not completely resolved (94).

The development of NS has been found in rare cases of mitochondrial disorders. Mutations in *COQ2*, located on chromosome 4q21, are associated with early onset of collapsing glomerulopathy-associated SRNS, with or without extrarenal symptoms (OMIM 607426) (95,96). In addition, mutations in decaprenyl diphosphate synthase subunit 2 (*PDSS2*), which is located on chromosome 6q21, led to both CoQ10 deficiency and NS in a patient with Leigh syndrome (OMIM 607426) (97). Mutations in mitochondrially encoded tRNA leucine 1 (*MT-TL1*) cause MELAS syndrome, which is sometimes associated with SRNS, characterized histologically by FSGS and extensive obliteration of podocyte foot processes (98). A single patient with NS and a genetic defect in mitochondrial respiratory chain activity has also been described (99).

Pathogenic mutations in the *MYH* gene, encoding the motor protein nonmuscle myosin heavy chain type II isoform A (*NMMHC-A*), are associated with the autosomal dominant giant-platelet disorders, which may include sensorineuronal deafness and glomerular disease. *NMMHC-A* acts as a component of the podocyte cytoskeleton contractile functions (100). Polymorphisms in *MYH9* were found to confer two to four times increased risk of ESRD in African-Americans compared with European Americans (101). Moreover, the presence of the same risk haplotype was associated with almost fivefold increased risk of FSGS (102).

Galloway-Mowat syndrome (GMS) is characterized by NS with central nervous system anomalies including microcephaly, psychomotor retardation, and macroscopic and microscopic brain anomalies (103). Other extrarenal disorders have also been reported, such as hiatus hernia, congenital spondylorhizomelic shortness, and diaphragmatic defects. NS appears usually at the age of a few months (0–34 months) and kidney biopsy may show MCNS, FSGS, DMS, or even mesangioproliferative glomerulonephritis. GMS is an autosomal recessive disorder, but the genetic defect is still unknown. In addition to GMS, there are solitary reports on other, unique combinations of NS and nonrenal defects.

### 64.13 DIAGNOSIS OF NS

NS is easily detected in newborns, infants, and children. Edema, hypoproteinemia, hyperlipidemia, and heavy proteinuria are the cardinal signs of NS. The typical

findings in full-blown NS include serum albumin level <10–20 g/L and urinary protein 2–100 g/L (after serum albumin has been corrected >15 g/L). The severity of proteinuria, however, shows variation and can be quite modest in the beginning. Serum creatinine can be normal during the first weeks or months. On the other hand, SRNS associated with DMS or FSGS often progresses to renal failure quite rapidly (6).

The exact etiologic diagnosis behind NS is much more difficult to unravel (104–106). The etiologic diagnosis, however, is helpful in assessing therapy and prognosis, in the follow-up of possible associated symptoms, and in genetic counseling of the family. Possible renal and nonrenal malformations, abnormalities of genitalia (karyotype), and neurological and ocular defects should be searched for, because they may give a clue to the etiology and help starting mutation search from the most likely gene. In newborns, placental weight >25% of birth weight is typically present in classic CNF, but may be seen in other entities with congenital NS. The indications for renal biopsy are not quite clear. Histological lesions, such as FSGS, MCNS, and DMS, are not specific for the gene defect involved. On the other hand, histology and clinical findings give a clue to the possible etiology. Severity of the histological lesions also helps to assess the treatment strategies.

In newborns with proteinuria during the first days of life, possible *NPHS1* mutations should be screened, followed by *NPHS2* analysis (104). If disease-causing mutations are found, kidney biopsy is perhaps not needed. If kidney biopsy has been performed and shows FSGS histology and/or signs of renal failure, search for *NPHS2* mutations is the first option in newborns as well as in older children. In these cases, if no mutation is detected, analysis of *NPHS1*, *WT1* and *PLCE1* can be performed (107). On the other hand, *WT1* and *PLCE1* analyses are indicated in all cases with DMS histology (108). In juvenile and adult patients with sporadic or autosomal recessive SRNS, screening for *NPHS2* mutations is the first step. A pR229Q change together with a disease-causing mutation is often found in adult-onset FSGS. In adults with autosomal dominant SRNS, screening for *INF2*, *TPRC6*, and *ACTN4* is indicated.

For the clinician, the situation is complicated: several genes can cause NS with overlapping phenotypes. Sequencing several genes one after the other takes time and is costly. However, if causative mutations are found the situation regarding treatment, prognosis as well as risk of recurrence and possibilities for prenatal diagnostics become much more clear. Careful clinical investigations to detect the possible syndromic cases as well as the suggested order of studying the genes in question hopefully helps in finding the etiologic diagnosis with reasonable effort.

Prenatal diagnosis of CNS by genetic analysis is feasible if the mutations in the family are already known.

It can be assumed that the combination of mutations in the family in question most probably leads to similar age of onset and severity as in the affected individuals in the same family. In case of no family history, CNF can still be detected prenatally based on elevated alpha-fetoprotein (AFP) in maternal serum and amniotic fluid. If the AFP concentration in amniotic fluid is very high and the ultrasound examination does not reveal fetal anencephaly or other malformations, CNF is a probable diagnosis. However, heterozygous fetal carriers of NPHS1 mutations may have temporarily elevated AFP levels in amniotic fluid and maternal serum and repeated measurement of amniotic fluid AFP before the 20th week of pregnancy is recommended in cases with high AFP levels (109). Prenatal diagnosis in families with a known risk for CNS should be based on mutation analysis whenever possible. If the mutations are known in advance, the results can be obtained rapidly. Sequencing of the possible genes is also possible, but it may not succeed in the short time frame during pregnancy.

## 64.14 MANAGEMENT OF NS PATIENTS

### 64.14.1 Supportive Therapy

The magnitude of the protein loss into urine is crucial for therapeutic decision making in patients with NS. Heavy and constant proteinuria (5–100 g/L) inevitably leads to life-threatening edema, and protein substitution by parenteral albumin infusions is mandatory (26). On the other hand, patients with moderate proteinuria (1–5 g/L) may manage without albumin substitution, especially if proteinuria is associated with renal failure and reduced urinary output. Patients with constant heavy proteinuria often have low levels of serum thyroid-binding globulin and thyroxine substitution is recommended. Imbalance of plasma coagulation factor levels contributes to hypercoagulability and risk for thrombosis, and the use of warfarin, aspirin and dipyridamole therapy has been recommended. Anti-thrombin III (50 U/kg) may be given before surgical procedures. Because of urinary losses of immunoglobulin, prophylactic use of antibiotics and immunoglobulin has been recommended, but in our experience, they are not helpful and may induce resistant bacterial strains. A high degree of suspicion for septic infections is warranted in NS patients. Infants with severe NS have traditionally been treated with a high-energy (130 kcal/kg/day) and high-protein (3–4 g/kg/day) diet. Glucose polymers are given to increase energy intake, and a mixture of rapeseed and sunflower oil is given to balance lipid levels. The children also receive vitamin D<sub>2</sub> (400 IU/day), multivitamin preparations, magnesium (50 mg/day) and calcium (500–1000 mg/day). Most infants need a nasogastric tube to guarantee their energy intake.

### 64.14.2 Medication and Kidney Transplantation

In nongenetic forms of NS (SSNS and SRNS) immunosuppressive medication with prednisone, calcineurin inhibitor (cyclosporine A (CsA), tacrolimus), antimetabolite (cyclophosphamide, chlorambucil, mycophenolic acid) or anti-CD20 antibodies (rituximab) often bring the disease into remission (110,111). Use of immunosuppressive drugs in hereditary forms of NS has traditionally been regarded unhelpful. However, few patients with proven hereditary SRNS and partial remission induced by Cs A have been reported (65,112). CsA and perhaps also glucocorticoids have a direct effect on podocyte cell signaling and maintenance of the actin network, which may explain the few cases with beneficial effects (113,114). In a recent report, the use of CsA, however, showed little effect in patients with genetic SRNS (115).

Reduction of protein losses by antiproteinuric drugs, ACE inhibitors, and indomethacin has been reported (26). These drugs lower the perfusion pressure in the glomerulus and have direct effects on the podocyte functions., e.g. nephrin expression (116), which lead to reduced protein leakage. In our experience, patients who have severe NPHS1 mutations (such as Fin-major and Fin-minor) do not respond to this medication. On the other hand, patients with mild (missense) mutations in podocyte genes may show a reduction in protein excretion and treatment with “antiproteinuric therapy” with ACE inhibitors is worth trying.

Renal transplantation is an established mode of therapy for children with NS not responding to medical therapy. Overall, the results of kidney transplantation in NS are quite similar to those obtained in other etiologies. Patient survival at 5 years is over 90% and graft survival over 80% in registry databases and in single centers (26). Recurrence of NS in the graft is rare but has occurred in 30% of the CNF children homozygous for Fin-major mutation. Antinephrin antibodies have been observed in these children after transplantation. Treatment of the recurrence with cyclophosphamide, plasmapheresis and anti-CD20 often leads to remission (117,118). The recurrence rate of NS in FSGS is in general about 30%. However, in hereditary FSGS this proportion is lower, about 8% (104).

## 64.15 CONCLUSIONS

Our knowledge on the genetic basis of NS has greatly increased during the past decade. Podocyte proteins play an important role in glomerular sieving and their genetic defects result in proteinuria and NS. Mutations in the NPHS1 gene lead especially to congenital NS, whereas NPHS2 mutations can cause NS at any age. The third important gene is WT1, which may cause syndromic and isolated NS. In addition, several other podocyte genes are responsible for rare cases of early- and late-onset NS.

Gene diagnostics is crucial in many cases with NS not responding to medical therapy.

## CROSS REFERENCE

Chapter 66.

### Biographies

**Hannu Jalanko, MD, PhD**, is a specialist in pediatric nephrology and transplantation. He has worked at the Children's Hospital, University of Helsinki, since 1984. During the past 10 years he has been the Head of Pediatric Nephrology and Transplantation Division at the Children's Hospital. He was appointed as professor in 2009. His research interests are nephrotic kidney disorders and management of pediatric transplant patients. He has published 160 original articles in these fields. He has acted as a section editor in journals of Pediatric Nephrology and Pediatric Transplantation and as an editorial board member of Transplantation; he is a member of the European Society of Pediatric Nephrology (ESPN) and American Society of Nephrology (ASN).

**Helena Kääriäinen, MD, PhD**, is a specialist in medical genetics. She started her career at the Family Federation of Finland, which is a nonprofit organization providing counseling, education and information in medical genetics. From 2003 to 2007 she was Professor of Medical Genetics at the University of Turku, Finland. Since then, she has been a Research Professor at the National Institute for Health and Welfare. She has been a board and executive board member of the European Society of Human Genetics (ESHG) since 2001, and Secretary General of the society during 2004–2010. In Finland, she has been a board member and President of the Finnish Society of Medical Genetics, and a member of several national and European committees related to genetics and research ethics. Her research interests are rare disorders, including rare renal diseases, genetic testing and counseling. She has written and edited books for medical doctors and lay people.

## Renal Tubular Disorders

*Richard E Hillman*

Metabolic Screening Laboratories, University of Missouri Hospital  
and Clinics, Missouri, MO, USA

### 65.1 INTRODUCTION

Disorders of renal tubular function must be divided both by the segment of the tubule involved and by the substrate(s) whose transport is affected. Molecules are reabsorbed by mechanisms that are both specific and saturable. In addition, there is some suggestion that the entry step of substrates into the renal tubule from the brush border side (the lumen) is under different genetic control from the exit step through the basolateral membranes into the blood.

In the past 10 years most of the transport proteins involved in specific transport systems have been identified and mapped. Reviews of the genes involved in transport of amino acids have been published by Verrey et al. (1) and by Broer (2). (The genes are identified with the specific defects listed later.) However, the identification of the transport proteins has still left much to be explained. For example, it is unclear why a mutation in a transport protein may be expressed only in the kidney, only in the gut, or in both, with differing clinical manifestations. There is not yet a good correlation with specific mutations and clinical severity in most cases. A few defects have yet to be identified.

Transport in the proximal tubule is largely energy dependent and is driven by oxidative metabolism. Experimentally it can be supported by acetate, lactate, and a variety of other organic acids. The distal tubules, and particularly the collecting ducts, are more dependent on energy derived from glycolysis. Many substrates are cotransported with sodium, and the driving force for movement across membranes is provided by the electrochemical potential difference generated by  $\text{Na}^+$  and  $\text{H}^+$  movements. Thus, inherited defects in energy metabolism, such as those in cytochrome C oxidase, and compounds such as heavy metals, which interfere with energy metabolism, can have effects on many different transport systems in the tubule. Several of the specific defects in energy metabolism, particularly the mitochondrial defects, have also been mapped.

Most disorders of transport involve defects in the proximal tubule. Clinically significant systemic disease

is produced by generalized transport defects and defects in bicarbonate, phosphate, and L-carnitine reabsorption. Defects in cystine reabsorption cause stones. Defects in neutral amino acid transport, when also present in the intestine, can cause Hartnup disease. However, many of the defects in transport, although genetically well defined, were thought to be of little clinical significance. There is now some suggestion that they may be important to the nutrition of seniors.

### 65.2 GENERALIZED DISORDERS OF TUBULAR FUNCTION (FANCONI SYNDROME)

The Fanconi syndrome is a generalized tubular disorder that leads to multiple transport abnormalities, including increased urinary loss of several organic substrates—amino acids, glucose, bicarbonate, and organic acids—and the loss of inorganic ions essential for mineral homeostasis—calcium, magnesium, sodium, potassium and, perhaps most important clinically, phosphorus (3). Clinically, the syndrome is usually defined by the combination of glucosuria, phosphaturia, generalized aminoaciduria, and renal tubular acidosis (RTA). In addition there is usually increased renal excretion of small-molecular-weight proteins. These metabolic abnormalities can lead to metabolic bone disease (rickets or osteomalacia) and stunted growth. Water-soluble vitamins are also lost into urine.

The Fanconi syndrome can be caused by a variety of inherited diseases and environmental factors that are toxic to the transport mechanisms in the proximal tubule. Inherited causes are familial idiopathic cystinosis; disorders of phosphorylated sugar metabolism, including galactosemia, glycogen storage disease, and hereditary fructose intolerance; Lowe syndrome; Wilson disease; tyrosinemia; medullary cystic disease; and rickets with secondary hyperparathyroidism. In the absence of other known diseases, it can also exist in an isolated form that is inherited as an autosomal recessive or dominant trait and in an X-linked recessive form with nephrolithiasis and renal failure, which although discussed here, could

be considered a form of RTA. In the general population the most common causes of childhood Fanconi syndrome are probably cystinosis and galactosemia. In the inner cities, lead poisoning may be the leading noninherited form.

The clinical presentation of the Fanconi syndrome (4) depends on the age of the patient and the other manifestations of the primary disease. Idiopathic Fanconi syndrome may manifest itself primarily as bone disease or as a gastrointestinal problem with vomiting, anorexia, constipation probably due to volume depletion, and chronic acidosis or can be found incidentally on routine urine analysis. The diagnosis of idiopathic Fanconi syndrome can only be made after an exhaustive search for other primary causes.

Families with autosomal dominant inheritance have been reported by Luder and Sheldon (5), Ben-Ishay and colleagues (6), Hunt and colleagues (7), and in four successive generations by Smith and colleagues (8). All these families with dominant inheritance were reported to have mild disease and were termed the adult Fanconi syndrome. However, Patrick and associates (9) reported in a follow-up of Luder and Sheldon's family that three members had developed renal failure. Interfamilial and intrafamilial clinical variation has been great. Some patients have only had the urinary findings without overt clinical expression, whereas others have had severe rickets. It was stated in 1992 (10) that 11 families were described. The gene for adult Fanconi syndrome has been mapped to chromosome 15q15.3 by Lichter-Konecki and colleagues (11).

Two autosomal recessive forms have been differentiated. In the severe childhood form the picture is much like cystinosis, and some questions must be raised whether the early reports of this mode of inheritance might not represent undiagnosed secondary causes of this syndrome. The most convincing pedigree is that of Klajman and Arber (12) who described a consanguineous Iraqi Jewish family with six affected siblings. The existence of an autosomal recessive adult form of the disease has been called into question. Dent and Harris's (13) family was shown by Brenton and colleagues (14) to have a dominant pattern of inheritance.

A huge family, of Irish descent, with X-linked nephrolithiasis, nephrocalcinosis, renal tubular dysfunction, and renal insufficiency was described by Frymoyer and colleagues (15). Wong and colleagues (16) reported five additional families. Scheinman and colleagues (17) performed linkage analysis on 102 members from five generations in the family reported by Frymoyer's group. Linkage (LOD score 5.91) was established to Xp11.22 (probe DXS255) with 3.6% recombination. In five unrelated British families, Pook and colleagues (18) mapped the disease to the same position using four different markers. One of these families had a microdeletion using the DXS255. The gene has been definitely identified by Schurman and colleagues (19) as

the *CLCN5* gene, which is also the gene that causes the similar Dent disease.

### 65.3 DISORDERS OF AMINO ACID TRANSPORT

Except for tryptophan and perhaps homocysteine, which are tightly bound to protein, amino acids are filtered freely by the glomerulus. Most amino acids are normally reabsorbed in the proximal tubule with only very small amounts remaining in the urine. Glycine and histidine, which are less efficiently reabsorbed than the other amino acids, account for most of the  $\alpha$ -amino nitrogen found in the urine. Only very small infants, particularly premature babies, excrete significant quantities of the other amino acids. In these infants alanine, proline, hydroxyproline, serine, and threonine are commonly present. Cystine is also seen in premature and occasionally in other newborns. It is now a more common finding because cystine is added to infant formulas.

Amino acids are reabsorbed by energy-dependent mechanisms of high specificity (20). In most cases transport is coupled to the movement of sodium ions. Essentially, the transport systems can be considered group specific. The amino acid transport systems are as follows:

- Neutral amino acid system L (leucine preferring)
- Neutral amino acid system A (alanine preferring)
- Iminoglycine system
- Acidic amino acid system
- Dibasic amino acid system (includes cystine)

At least two transport systems are present for neutral amino acids with differing affinities. At least one transport system is present for amino acids containing two ammonium groups (the dibasic amino acids plus cystine). This transport system is the first in which a definite membrane-associated protein has been cloned and mapped. One system is present for acidic amino acids and another for the combination of glycine, proline, and hydroxyproline (the iminoglycine system). Studies in animals suggest that secondary systems with lower affinity are also present for the same substrates (21,22). This concept has been used to explain some of the variant amino acid disorders in humans, in which the urine pattern does not correspond to the listed systems. The transport systems described are all present in the brush border of the tubule and the gut and have been observed in a variety of cell types. A defect in basic amino acid transport in the basolateral membrane of the cell has been described for the dibasic amino acids, lysinuric protein intolerance (23). This system has a different inheritance and different affinities for amino acids than the dibasic system found in brush borders.

The genetics of amino acid transport are not always clear. In some families, defects are found only in kidney tubules, in some only in gut, and in others in both. It is hoped that the identification and mapping of proteins involved in transport will help to clarify these issues.

### 65.3.1 Glycine and the Imino Acids

Joseph and colleagues (24) described a child with marked increases in the urinary excretion of proline, hydroxyproline, and glycine. Since then numerous other reports have been published, and newborn screening studies (25) have reported an incidence as high as 1 in 20,000 in the general population. Initial association of iminoglycinuria with a variety of neurological disorders (e.g. deafness, blindness, mental retardation) was reported. However, family studies and population screening suggest that this is a benign condition inherited as an autosomal recessive trait (26). This transport system has a much higher affinity for the imino acids than for glycine (27). Heterozygotes may excrete glycine in the urine. This probably explains the dominant glycinuria reported in three generations by Greene and colleagues (28). However, Scriver (29) has suggested that there may be several different forms of hyperglycinuria. This transport system is quite late developing in humans (30), and these amino acids are commonly elevated in the urine of newborn infants, particularly premature ones. Like many of the other disorders of amino acid transport in the kidney, a defect in the intestine may or may not also be present (31). The primary importance of this hereditary condition is that it can be mistaken for a primary defect in glycine metabolism or a secondary defect due to organic aciduria. The molecular defect in this combination has not been described.

### 65.3.2 Dibasic Amino Acids and Cystine

**65.3.2.1 Classic Cystinuria.** Cystinuria is not only a clinically significant disease but also important historically because it was one of the original inborn errors reported by Garrod in his famous Croonian lectures (32). McKusick (33) quotes Marcet as suggesting in 1817 that the disease was familial. In classic cystinuria the urinary excretion of lysine, ornithine, arginine, and cystine is greatly increased compared to normal (34). Although the absolute increase in cystine is less than that of the other amino acids, because it is far less soluble, it forms stones. Serum amino acids are normal, and no nutritional deficiency in patients has been demonstrated. The mutation in this transport system was also the first that was found for amino acids.

Three hereditary patterns of excretion have been described in heterozygotes for classic cystinuria (35). Homozygotes, including compound heterozygotes between two types, cannot be distinguished. Heterozygotes can be separated based on their pattern of urinary amino acids and whether or not they also have an intestinal defect. Type I heterozygotes have normal excretion of cystine in their urine. Types II and III heterozygotes have increased excretion in their urine. They can only be distinguished by studying intestinal transport. Type II heterozygotes have a transport defect in the gut, but type III do not.

The incidence of clinical cystinuria is reported to vary widely in different populations. In Sweden the incidence is reported to be only 1 in 100,000 (36), whereas in Libyan Jews it is reported to be as high as 1 in 2500 (37). Neonatal screening suggests a high incidence in many populations (1 in 15,000 in Boston, 1 in 11,000 in Vienna, and 1 in 17,000 in Sydney), but these figures must be accepted very conditionally because of the increased secretion normally noted in newborns and particularly because of the observation by Scriver (personal communication, 1986) that newborn heterozygotes are difficult to distinguish from homozygotes. Our own observations suggest that the incidence is particularly high in the Old Order Mennonites, both in Pennsylvania and Missouri.

Cystinuria is the first amino acid transport disease in which the molecular defect was identified and mapped. Wells and Hediger (38) isolated a protein related to amino acid transport in the rat. Lee and colleagues (39) located a similar DNA out of a human library and localized it to chromosome 2p (SLC3A1 amino acid transferase gene). Pras and colleagues (40) demonstrated linkage of this gene to cystinuria. Calonge and colleagues (41) have now demonstrated six different missense mutations in eight different families with cystinuria (30% of all defects in the affected). Gasparini and coworkers (42) indicated that all mutations in SLC3A1 were in patients with type I disease. Cystinuria types II and III have been linked to the SLC7A9 amino acid transport gene by several authors (43).

#### 65.3.2.2 Other Forms of Dibasic Aminoaciduria.

Cystine excretion in the absence of other dibasic amino acids has been reported (44). The two siblings with this condition were without stones but were only 2 and 4 years old when reported. Dibasic aminoaciduria in the absence of cystine excretion was reported in 13 members of a family (45). These patients were also asymptomatic.

The description of lysinuric protein intolerance has led to the first documentation of a basolateral transport defect for dibasic amino acids (but not cystine) (46). This disorder leads to a marked protein intolerance because of hyperammonemia and suggests that the urea cycle is not perfect but requires the intake of the dibasic amino acids. The defect can be partially overcome by citrulline, which is not transported by the same system. The disease has been reported throughout the world but has a particularly high incidence in Finland (1 in 60,000).

### 65.3.3 Neutral Amino Acids

Hartnup disease is primarily a neutral amino acid transport defect. However, histidine, glutamine, and asparagine are also increased in the urine. It can be distinguished from a generalized aminoaciduria because the other amino acids are not increased. Often the disease is diagnosed from urine because of the presence of indoles and tryptamine produced by bacteria,

owing to malabsorption of tryptophan by the gut. Stool amino acids, when measured, are increased. The gene for Hartnup disease has been definitely identified with the SLC6A19 transporter gene on 5p15 in the original family with this disorder by Kleta and colleagues (47). The clinical manifestations of the disease are very variable (48). The patient may have any combination of cerebellar ataxia, emotional instability, delayed development, severe retardation, and a pellagra-like rash. However, recent evidence suggests that the renal defect in the absence of an intestinal transport defect is of less significance than the combined defect or an intestinal defect alone ((49); Scriver, personal communication, 1987). Many of the clinical manifestations have been believed to be due to tryptophan malabsorption, leading to niacin deficiency. However, in the author's experience patients who have clinical manifestations other than rash (primarily developmental delay and ataxia) continue to have slow development even when receiving large amounts of niacin and a good protein intake. Magnetic resonance imaging in these patients leads one to speculate that a transport defect may also be present in the brain.

The disease appears to have an autosomal recessive inheritance. Several reports of consanguineous cases have appeared. There seem to be three forms of the disease. The classic form has defects in both the renal tubular and intestinal systems (50). The form of the disease usually detected on newborn screening has only urinary manifestations (25) and may be benign. A disorder affecting only the gut transport systems was described, which was associated with growth and developmental delay (49). Subsequently, we have found another family with two affected siblings and lesser degrees of intestinal loss of amino acids in the mother and two siblings who were normal. This strongly supports autosomal recessive inheritance.

### 65.3.4 Acidic Amino Acids

Massive excretion of aspartic and glutamic acids has been reported twice in single patients (51,52). Presumably this condition has an autosomal recessive inheritance. The clinical manifestations in the two patients were quite different, and the significance of this condition is unknown.

## 65.4 RENAL TUBULAR ACIDOSIS

### 65.4.1 Proximal Renal Tubular Acidosis (Type II RTA)

Proximal RTA is caused by bicarbonate loss only in the proximal tubule. Because most bicarbonate is reabsorbed more distally, when the filtered load is decreased by a fall in serum bicarbonate, normal acidification mechanisms in the distal tubule can still lower the urine pH.

The serum electrolytes demonstrate a hyperchloremic acidosis.

RTA type II occurs as part of the Fanconi syndrome. Nearly all isolated cases have been in young boys, most before 2 years of age (3,53). The great predominance of males (4:1) suggests an X-linked recessive form of inheritance. This mode of inheritance has not been proven, however, because no family history can be demonstrated in a majority of cases (54). A mild RTA II with dominant inheritance has been studied (55).

### 65.4.2 Distal Renal Tubular Acidosis (Type I RTA)

In type I RTA bicarbonate is lost in the distal tubules. This disease presents with nephrocalcinosis, fixed urinary specific gravity, a low serum bicarbonate, and hypocalcemia. The bone manifestations are very variable but may be severe. Chaabani and colleagues (56) recently reported a large pedigree in which 28 members had RTA I, the clinical presentation being quite variable. Some had nephrocalcinosis and growth retardation, whereas others were clinically unaffected. An unstable form of carbonic anhydrase B in red cells was reported by Kondo and colleagues (57), but no correlation with clinical states is yet available.

RTA I has an autosomal dominant inheritance. Randall's (58) follow-up of the pedigree described with Targgart (59) clearly shows male to male transmission. Linkage is now established to 17q21-q22. This is the chloride-bicarbonate exchanger gene AE1 (now called SLC4A1 transporter gene) (60).

A distinct form of RTA I with perception deafness was reported by Konigsmark (personal communication, 1966), and Nance and Sweeney (61) provided evidence for autosomal recessive inheritance. Reports of carbonic anhydrase activity in this condition have varied widely, and the association is unclear. The condition is, however, clearly different from either classic RTA I or carbonic anhydrase II deficiency, described later.

### 65.4.3 Carbonic Anhydrase II Deficiency

RTA that is primarily distal but also proximal was described by Sly and colleagues (62-64) in three sisters with osteopetrosis and cerebral calcifications. Carbonic anhydrase II is found in both kidney and brain and was deficient in the patients and decreased in the obligate heterozygotes. About half of all the subsequently reported cases have occurred in families of Arab descent in the Middle East or North Africa. The gene has been localized to chromosome 8q22 (65,66). At least eight different mutations have now been described in patients with this deficiency. Hu and colleagues (67) found the same novel splicing mutation in six unrelated Arab families, and this should be useful for diagnosing patients in this ethnic group by polymerase chain reaction.

## 65.5 DISORDERS OF SUGAR TRANSPORT

At least two transport systems mediate the absorption in the gut or the reabsorption of sugars in the proximal tubule. The most important is the system for glucose and galactose. Also present in the proximal tubule are systems for the reabsorption of other sugars. Fructose is not actively transported by the tubule, and the condition known as fructosuria is due to overflow rather than a transport defect. As with the amino acid transport disorders, defects have been described that affect the intestine as well as the kidney. Because heterozygotes for these disorders may spill small amounts of sugar into the urine, these disorders have been described as having dominant modes of inheritance (68). However, heavy excretion is seen only in homozygotes and the conditions are considered autosomal recessive.

### 65.5.1 Renal Glycosuria

Clinically, renal glycosuria may be considered as two disorders. First, patients may have a low threshold for glucose but a normal total capacity to reabsorb it. Thus, these patients will spill glucose into their urine at normal serum concentrations, but their total daily loss is not great. This disorder is important mainly because it may be confused with diabetes mellitus and because a low renal threshold for glucose may make urine monitoring of a diabetic difficult. Second, patients may have a decreased capacity to reabsorb glucose with or without a decreased threshold. These patients may spill very large amounts of glucose in a day, sometimes as much as 100 g. These two defects appear to be allelic. Elsas and Rosenberg (69,70) showed that both types of defects can appear in the same family and that compound heterozygotes have clinical glycosuria. Oemar and colleagues (71) described a family in which glucose reabsorption appeared to be completely absent. Some of these patients have polydipsia and polyuria, and many of the women have yeast infections of the vagina. Most, however, have few clinical symptoms. Kanai and colleagues (72) recently provided evidence that the defect in these patients is in the low-affinity  $\text{Na}^+$  glucose cotransporter in the proximal tubule. This gene has not yet been studied in the clinically more important disease of the intestine and kidney, glucose–galactose malabsorption.

Linkage was initially related to the HLA site, but more recently it has been suggested that it is related to the low-affinity sodium/glucose cotransported SLC5A2 on chromosome 16 (72). A specific mutation in this gene (now labeled SLC5A2) was reported by van den Heuvel and colleagues (73).

### 65.5.2 Fructosuria

Fructosuria in the absence of fructose intolerance (fructose phosphate aldolase deficiency) is not a renal tubular

disease. Instead, this benign condition is the result of a defect in hepatic fructokinase. It is inherited as an autosomal recessive trait (74). The gene has been mapped to 2p23.3 by Bonthron and colleagues (75) who demonstrated the first mutations.

### 65.5.3 Pentosuria

Pentosuria was also one of the original inborn errors described in the Garrod lectures (32). Patients excrete 1–4 g of pentose, primarily 1-xylulose, daily (76). It is a benign condition that occurs primarily in Ashkenazi Jews of Polish origin and in Lebanese. This condition, like fructosuria, is usually a disorder of metabolism rather than transport. Wang and Van Eys (77) demonstrated that the defect is in the enzyme NADP-xylitol dehydrogenase. Heterozygotes have intermediate levels of the enzyme, confirming its autosomal recessive mode of inheritance.

## 65.6 HYPOPHOSPHATEMIC RICKETS

Hypophosphatemic rickets behaves as an X-linked dominant trait in most families. However, Scriver and coworkers (54) described an autosomal dominant pedigree. See Chapter 153 for a detailed discussion of this disorder.

## 65.7 CONCLUSION

The renal tubules reabsorb 80–98% of filtered small molecules by energy-dependent mechanisms. Disorders, primary or secondary, that interfere with these mechanisms can cause loss in the urine of sugars, amino acids, bicarbonate, phosphorus, and other cations, as well as a variety of organic acids. Specific transport systems are under genetic control. Thus, inherited disorders can affect the reabsorption of only one or a small group of compounds. Defects altering energy metabolism can produce a more generalized loss of renal tubular mechanisms. With the notable exceptions of bicarbonate and phosphorus, unless an intestinal defect is also present, these disorders produce little systemic disease and have not yet been implicated in nutritional deficiencies, although there is now some suggestion that they may be import in seniors. Cystine transport deficiency produces problems primarily because of the low solubility of this compound. Nonetheless, these disorders are important to recognize because they cause confusion with defects in metabolism, where increased serum levels of a compound cause the filtered load to exceed the tubules' capacity for reabsorption.

WAGR – Wilms’ tumor, aniridia, genitourinary abnormalities, mental retardation

### 66.1 TUMORS OF THE KIDNEY

#### 66.1.1 Wilms’ Tumor

Wilms’ tumor (nephroblastoma) is the most common solid tumor in childhood and affects approximately 1 in 10,000 children. The median age at diagnosis is 3–4 years, with most children affected by age 6. Approximately 5% of patients have bilateral tumors, and these children are younger at diagnosis (mean 26 months) than those with unilateral tumors (mean 36 months) (1). Wilms’ tumor is believed to arise from remnants of immature kidney, and microscopic examination may show structures that resemble stages in normal renal development. Most tumors show a triphasic histology, with variable proportions of persistent blastemal cells, dysplastic tubules, and supporting stroma. The parallel between normal renal development and Wilms’ tumor is reinforced by the high incidence of developmental abnormalities in children with Wilms’ tumor, approximately 5% having genitourinary abnormalities. In addition, many Wilms’ tumors arise in kidneys containing foci of persistent renal stem cells known as nephrogenic rests. These are rare in normal kidneys after 1 year of

age but can be found in up to 40% of unilateral and in almost all bilateral Wilms’ tumor kidneys (2). Analysis of the age of onset of bilateral and unilateral Wilms’ tumor by Knudson and Strong (3) was compatible with a two-hit model of tumorigenesis, as previously reported for retinoblastoma. However, familial Wilms’ tumor is rare. A number of genetic disorders are associated with a predisposition to Wilms’ tumor including WAGR syndrome (see later discussion), Denys–Drash syndrome (DDS), Beckwith–Wiedemann syndrome (BWS), hemihypertrophy, familial Wilms’ tumor, Perlman syndrome, Simpson–Golabi–Behmel syndrome (SGBS) and mosaic variegated aneuploidy syndrome. Although only 2% of patients have an associated genetic disorder, the analysis of these patients, particularly those with the WAGR syndrome, has been critical to the isolation of Wilms’ tumor genes.

##### 66.1.1.1 WAGR Syndrome and the WT1 Gene.

Approximately 1% of children with Wilms’ tumor have aniridia, compared with 1 in 50,000 of the general population. These children may also have other characteristic abnormalities associated with the WAGR syndrome (Wilms’ tumor, aniridia, genitourinary abnormalities, and mental retardation). Most children with the WAGR syndrome have cytogenetically visible chromosome 11 deletions involving band 11p13, and this observation formed the basis for the assignment and subsequent isolation of the aniridia (PAX6) and Wilms’ tumor suppressor (WT1) genes from chromosome 11p13. Wilms’ tumor does not complicate familial aniridia caused by intragenic PAX6 mutations, but children with sporadic aniridia and a contiguous deletion of WT1 and PAX6 (which are approximately 700kb apart) are at risk. In such cases aniridia is fully penetrant, but Wilms’ tumor occurs in only 50% of patients with WAGR deletions (4). Similarly, the occurrence and severity of genitourinary abnormalities and mental retardation are variable. Inclusion of BDNF in WAGR syndrome deletion is associated with obesity (5).

For patients with sporadic aniridia, the risk of Wilms' tumor is about 15% (6). Although most patients with Wilms' tumor and aniridia have a cytogenetically visible chromosome 11p13 deletion, Wilms' tumor can also occur in those with submicroscopic deletions. Molecular cytogenetic and genetic analysis can determine the extent of a deletion and hence the risk of Wilms' tumor (7).

WT1 encodes a zinc finger-containing protein. WT1 has multiple functions, and it may appear to have differing effects on cell proliferation in different cellular contexts (8). Alternative splicing can result in a variety of proteins (e.g. with inclusion or exclusion of 17 amino acids encoded by exon 5 and three amino acids (KTS: lysine, threonine, and serine) between zinc fingers 3 and 4) and the precise nature, and relative levels of WT1 isoforms are important in the regulation of WT1 function. The WT1 gene product has four zinc finger motifs at the C terminus and a proline-glutamine-rich domain at the N terminus, suggesting a role in transcriptional regulation. In some cases WT1 may act as a transcriptional activator, but it is also proposed to repress the expression of important growth factors such as IGF2, IGF1R, and epidermal growth factor receptor (9). Although a role for WT1 in RNA processing has been suggested, transcriptional regulation is the best established function (8). About 10% of Wilms' tumors have WT1 mutations, and loss-of-heterozygosity studies have implicated a further gene (WT2) in chromosome 11p15 (which may be imprinted, as chromosome 11p allele loss in Wilms' tumor preferentially affects the maternal chromosome) in the pathogenesis of Wilms' tumor (10). The frequency of germline WT1 mutations in nonsyndromic Wilms' tumor patients is small (approximately 2%), but occasionally a WT1 mutation can present with a unilateral tumor and no genitourinary abnormality (11).

Genitourinary abnormalities in the WAGR syndrome result from deletion of WT1. The expression of WT1 is tightly controlled during normal development, with the strongest expression occurring in the fetal kidneys, gonads, and mesothelium (12,13). Within the kidney, WT1 mRNA expression is strongest in the renal vesicles and glomerular epithelium. A variety of investigations have suggested that WT1 is involved in normal genital and gonadal development, including the specific expression of WT1 mRNA in the developing gonad (12,13), the finding of WT1 mutations in DDS and Frasier syndrome (see below), and the failure of gonadal development in transgenic mice homozygous for WT1 mutations (14). Individuals with familial aniridia and sporadic aniridia without WAGR syndrome have inactivating mutations (usually frameshift or nonsense mutations) in the PAX6 gene (15–17).

**66.1.1.2 Denys–Drash Syndrome.** DDS is a rare disorder characterized by a progressive glomerulonephropathy causing renal failure, genital anomalies, and Wilms' tumor (18,19). Not all patients have the complete triad, and nephropathy plus one of the other features

is sufficient to make the diagnosis. The nephropathy is characterized by the presence of focal or diffuse glomerulosclerosis and usually presents with proteinuria progressing to nephrotic syndrome and hypertension, and then end-stage renal failure by 3 years of age (18). Males (XY karyotype) with DDS usually have ambiguous genitalia or phenotypically normal female external genitalia (male pseudohermaphroditism). In addition, the internal genitalia are frequently dysplastic or inappropriate (19). XX individuals usually have normal female external genitalia but the internal genitalia are frequently dysplastic. Wilms' tumor in DDS presents early (mean 18 months) and is frequently bilateral.

Renal failure is the most common cause of death in DDS, but recent advances in the management of renal failure and renal transplantation in childhood are improving the prognosis. Nevertheless, the management of DDS is difficult. Affected patients require surveillance for Wilms' tumor. Bilateral nephrectomy is indicated in patients with renal failure receiving renal replacement therapy (19,20), but patients with screen-detected Wilms' tumor without renal failure may be treated by nephron-sparing surgery (21).

Molecular genetic analysis of DDS patients has demonstrated de novo germline WT1 mutations in most cases (reviewed in (18,19,22)). Most mutations affect the second and third zinc finger domains and the most common mutation is a missense mutation at codon 394 in exon 9. DDS mutations are predicted to alter or impair the DNA-binding function of the WT1 gene product. The genital abnormalities in DDS are more severe than those in the WAGR syndrome, suggesting that DDS mutations produce their effect on genital development by a dominant negative mechanism (23). However, Wilms' tumor does not occur in all DDS patients, suggesting that DDS mutations do not have a dominant negative effect in the pathogenesis of Wilms' tumor (23,24). The phenotype of Meacham syndrome (male pseudohermaphroditism with abnormal internal female genitalia comprising a uterus and double or septate vagina, congenital heart defect and diaphragmatic abnormalities) overlaps with that of DDS and Suri et al. (25) demonstrated that the two disorders are allelic.

**66.1.1.3 Frasier Syndrome.** This rare disorder is defined by male pseudohermaphroditism, streak gonads, and renal failure from focal and segmental glomerulosclerosis. Gonadoblastoma is frequent, but Frasier syndrome is distinguished from the related DDS by the absence of Wilms' tumor and a more slowly progressive glomerulopathy (end-stage renal failure usually occurs in adolescence or early adulthood). Germline WT1 mutations in the donor splice site in intron 9 were described in Frasier syndrome by Barbaux et al. (26). WT1 mutations associated with Frasier syndrome lead to loss of the +KTS WT1 isoform (see previous discussion) (27,28). Identification of the molecular basis of Frasier syndrome has enabled this disorder to be

diagnosed in females with normal female genital development and focal segmental glomerulosclerosis (29). Thus the +KTS isoform appears to be critical for renal and testicular development (30), but not for ovarian development or function.

**66.1.1.4 Beckwith–Wiedemann Syndrome.** BWS, a congenital overgrowth syndrome with an estimated incidence of 1 in 14,000, is characterized by a triad of major features: macroglossia, pre- or postnatal gigantism (>90th centile), and anterior abdominal wall defects (exomphalos, umbilical hernia, or diastasis recti). Minor features include earlobe creases or posterior helical rim pits (75% of cases), facial naevus flammeus (62%), visceromegaly (liver, kidney, spleen), and renal abnormalities (including nephromegaly) (62%) (31). Neonatal hypoglycemia is frequent and occasionally severe or prolonged. Less-common features include hemihypertrophy (25%), cardiac defects (9%), and cryptorchidism. Mental retardation is uncommon and is usually associated with a history of prematurity or the presence of chromosome 11 duplication. Facial dysmorphisms (maxillary hypoplasia and macroglossia) become less apparent with age, and although surgical tongue reduction may be indicated, bone age is advanced and growth rate tends to slow down during late childhood. Most cases of BWS are sporadic, but approximately 15% are familial, with autosomal dominant inheritance with incomplete (and parent-of-origin effects) penetrance and variable expression (see (32) and references within). Penetrance is more complete when the mother is the transmitting parent (33). An excess of multiple births, particularly female monozygotic twins discordant for BWS, has been noted in BWS, and there is an increased incidence of BWS in children conceived with assisted reproductive technologies, such as in vitro fertilization and intracytoplasmic sperm injection (ICSI) (34,35). A small number of BWS patients have duplications or balanced translocations or inversions of chromosome 11p15, and duplications are invariably of paternal origin, whereas chromosome 11 inversions or balanced translocations are of maternal origin (see (32)). In addition, approximately 20% of sporadic patients with sporadic BWS have uniparental disomy (UPD) of chromosome 11p15 (36,37). UPD in BWS patients arises as a postzygotic mitotic event, so that affected individuals are mosaic for normal cells and cells with paternal isodisomy, including chromosome 11p15.5. There is a strong association between UPD and hemihypertrophy, such that most patients with hemihypertrophy have UPD, and the hemihypertrophy appears to reflect the variation in the proportion of disomic cells between the two sides of the body (37). A clinical association between hemihypertrophy and Wilms' tumor was reported (38); and there is a higher risk of Wilms' tumor in BWS patients with UPD.

The genetics of BWS are complex, but the key factors are that genetic or epigenetic alterations within

an imprinted gene cluster at 11p15.5 result in loss of activity of the maternally expressed candidate growth suppressors CDKN1C and H19 and/or increased expression of the paternally expressed growth promoter IGF2 (insulin-like growth factor 2). Thus in BWS patients with paternally derived 11p15.5 duplications and those with UPD there is increased IGF2 expression from the additional paternal IGF2 alleles. Sporadic BWS children without UPD have epigenetic alterations at two imprinting control regions within 11p15.5, resulting in loss of imprinting of IGF2 (biallelic expression) or silencing of CDKN1C (see later). Although elevated IGF2 expression provides a plausible explanation for many features of BWS (39), the maternally expressed cyclin-dependent kinase inhibitor CDKN1C (p57KIP2) is also implicated and germline CDKN1C mutations occur in approximately 40% of familial cases and 5% of sporadic cases (40,41).

Imprinting of IGF2 is closely linked to that of the reciprocally imprinted (maternally expressed RNA) H19 gene, and the imprinting of IGF2 and H19 is regulated by an intergenic imprinting control region (IC1) that contains CTCF binding sequences. IC1 is differentially methylated (paternal allele methylated and maternal unmethylated), but a subset of BWS children (approximately 5%) have biallelic ICR1 methylation and biallelic IGF2 expression and silencing of H19 expression due to IC1 deletions or, more commonly, epimutations (32,42).

Molecular mapping of rare balanced translocation and inversion breakpoints associated with maternally inherited BWS led to the recognition of a second more proximal, imprinting control center (IC2) within the 11p15.5 gene cluster (43). Within an intron of the KCNQ1 (KVLQT1) gene, which maps between CDKN1C and IGF2, there is a differentially methylated region (KvDMR1, paternal allele unmethylated and maternal allele methylated), and about 50% of sporadic BWS cases have loss of methylation (biallelic unmethylated alleles) at KvDMR1 (44–46). Loss of maternal KvDMR1 methylation is associated with loss of maternal CDKN1C expression (46,47). There is a very high frequency of KvDMR1 loss of methylation in BWS children born after assisted reproductive technologies, and although IC2 defects may be caused by genetic alterations (48), epimutations are the most common cause of IC2 defects. Genotype–phenotype correlations can explain some of the phenotypic variability seen in BWS. Germline CDKN1C mutations and IC2 defects are associated with a high frequency of exomphalos, suggesting that inactivation of CDKN1C is a critical factor in the pathogenesis of exomphalos in BWS (41). Approximately 5% of BWS patients develop an embryonal neoplasm, most commonly Wilms' tumor, but hepatoblastoma, adrenal cortical carcinoma, and neuroblastoma also occur. In contrast to children with WAGR syndrome and DDS, in whom Wilms' tumor occurs at a younger age than in

sporadic cases, the BWS patients with Wilms' tumor are not younger at diagnosis. Instruction of the parents in weekly abdominal palpation is routinely recommended, and many authorities suggest regular renal ultrasound scans (e.g. every 3 months upto the age of 7 years), and in some cases, serum  $\alpha$ -fetoprotein estimates for hepatoblastoma detection. Wilms' tumor risk is highest in BWS children with UPD or IC1 defects (i.e. those with biallelic IGF2 expression), but Wilms' tumor has not been associated with germline CDKN1C mutations or IC2 defects (though other tumors may occur). Hence knowledge of the molecular subtype of BWS can influence the tumor surveillance program for BWS children. Morrison et al. (49) described a small group of patients with overgrowth, Wilms' tumor and biallelic expression of IGF2 and H19 silencing, but no other evidence of BWS. Furthermore, Scott et al. (50) detected 11p15.5 constitutional abnormalities (e.g. uniparental disomy, IC1 deletions and epimutations) similar to those in BWS in 3% of patients with apparently nonsyndromic Wilms' tumor (12% of bilateral cases).

**66.1.1.5 Simpson–Golabi–Behmel Syndrome.** This X-linked disorder is characterized by pre- and postnatal overgrowth, macrocephaly, coarse facies, cleft palate, central cleft of the lower lip, midline tongue groove, polydactyly, accessory nipples, and a variety of congenital cardiac, gastrointestinal, and genitourinary malformations (51,52). Affected males are at risk of embryonal tumors, including Wilms' tumor and neuroblastoma (53).

SGBS should be differentiated from other overgrowth syndromes, in particular BWS. Although X-linked, carrier females may show some expression, so that the X-linked inheritance pattern may superficially resemble the parent-of-origin effects seen in familial BWS (53).

Mutations in GPC3, a glypican gene, cause SGBS, and it suggested that GPC3 mutations might modify IGF2 function (54). A second locus for SGBS has been mapped to Xp22 (55). Li and coworkers (56) suggested that hepatoblastoma and nephroblastomatosis are part of the Simpson–Golabi–Behmel syndrome phenotype and identified GPC3 deletion in two patients previously diagnosed as having Sotos syndrome and Perlman syndrome. Surveillance for Wilms' tumor should be performed by renal ultrasonography every 3–4 months until age 7 years (57).

**66.1.1.6 Perlman Syndrome.** Wilms' tumor occurs frequently (45% of patients) and has an early onset (in the first year of life) in this autosomal recessively inherited disorder. Other renal features include nephromegaly and nephroblastomatosis. Although there are similarities to BWS (polyhydramnios, macrosomia, nephromegaly, and hypoglycemia), the distinctive facial dysmorphism (deep-set eyes, broad/depressed nasal bridge, everted upper lip, macrocephaly) allows the two conditions to be distinguished (58). Cryptorchidism is common, and cardiac defects and diaphragmatic hernia have been reported (59). Perlman syndrome is

associated with a high neonatal death rate, and three of four patients who survived the neonatal period were mentally retarded.

**66.1.1.7 Fanconi Anemia Complementation Group D1.** Fanconi anemia is an autosomal recessively inherited disorder characterized by bone marrow failure and congenital anomalies. A subtype of Fanconi anemia, D1, is caused by homozygous mutations in BRCA2. Children with this form of Fanconi anemia are at risk of developing childhood tumors including Wilms' tumor (60).

**66.1.1.8 Mosaic Variegated Aneuploidy.** This rare autosomal recessive disorder is caused by mutations in BUB1B, which encodes BUBR1, a key protein in the mitotic spindle checkpoint (61). Mosaic variegated aneuploidy is characterized by mosaic aneuploidy (usually trisomy or monosomy), growth retardation, developmental delay and microcephaly, eye and other anomalies and a high risk of cancer including Wilms' tumor.

**66.1.1.9 Familial Nonsyndromic Wilms' Tumor and Other Wilms Tumor Genes.** Approximately 1% of Wilms' tumor patients have an affected relative. Familial predisposition is inherited as an autosomal dominant trait with incomplete penetrance (62). Germline mutations in WT1 are a rare cause of familial Wilms' tumor (unsurprisingly, in view of the importance of WT1 for normal genital and gonadal development), but Pelletier and colleagues (63) reported a father–son pair with Wilms' tumor (and hypospadias and cryptorchidism in the son) associated with a germline WT1 mutation. There is a paucity of data on the recurrence risk of Wilms' tumor, although Crawford (64) suggested that the risk for siblings of unilateral sporadic cases was approximately 0.1%, but that the risks were significantly higher in families with two affected siblings (33%) and for the children of survivors of Wilms' tumor: perhaps 2–10% for patients with unilateral tumors and approximately 33% for patients with bilateral or familial tumors. In addition to 11p15.5 abnormalities (see above), genetic linkage studies mapped Wilms' tumor susceptibility genes (FWT1 and FWT2) to chromosomes 17q12–q21 and 19q13.3–13.4, respectively (65,66) with evidence for further locus heterogeneity and a later age of onset than in sporadic cases in FWT1-linked families (67–69).

Germline DICER1 mutations in addition to predisposing to pleuropulmonary blastoma may also be associated with multilocular cystic nephroma and, rarely Wilms tumor (70,71).

The X chromosome gene WTX was identified through the detection of somatic mutations in sporadic Wilms' tumor and shown to be a negative regulator of wnt signaling (72,73). Germline mutations in WTX were found in osteopathia striata congenita with cranial sclerosis (74). Although germline WTX mutations have not been associated with Wilms' tumor (or other cancers), precursor lesions (nephrogenic rests) have been described in one mutation carrier (75).

### 66.1.2 Renal Cell Carcinoma

Renal cell carcinoma (RCC) is the most common adult renal neoplasm and accounts for almost 90% of malignant kidney tumors. Up to 3% of patients with RCC have an inherited predisposition. The most frequent cause of familial RCC is von Hippel–Lindau (VHL) disease, a multisystem familial cancer syndrome with variable expression. Tumor histopathology is useful in investigating the basis of familial RCC. VHL-related tumors are invariably clear cell, but familial non-VHL clear cell RCC (FCRC) also occurs (see later discussion) and rare cases of clear cell RCC may be associated with constitutional balanced rearrangements involving the proximal region of the short arm of chromosome 3 (76). Hereditary papillary RCC is associated with germline MET proto-oncogene mutations in many cases. Birt–Hogg–Dube (BHD) syndrome is associated with RCC susceptibility, and renal cancer may be associated with germline mutations in the Krebs cycle enzyme genes fumarate hydratase (FH) and succinate dehydrogenase (77). Although patients with tuberous sclerosis may rarely have an increased risk of RCC (78), angiomyolipoma is the most frequent renal tumor in this disorder.

**66.1.2.1 von Hippel–Lindau Disease.** VHL disease is autosomal dominantly inherited, with a minimal birth incidence of 3 per 100,000 persons and a prevalence of 2.5 per 100,000 (79). Expression of disease is variable, but the most frequent manifestations are retinal (60% of patients), cerebellar (60%), spinal (13–44%) and brain-stem hemangioblastoma (18%); RCC (28%); pheochromocytoma (10%); and renal, pancreatic, and epididymal cysts (77,80). Most patients with VHL disease present in the second or third decades with retinal or cerebellar hemangioblastomas, but the onset may rarely be in infancy and penetrance is almost complete by age 60 years. The risk of RCC is influenced by the underlying mutation (see later), but in many cases the risk of an affected patient developing RCC is approximately 70% by age 60 (80) (Figure 66-1). As with other familial cancer syndromes, patients with VHL disease have a greatly increased risk of RCC and tumors develop at an early age and are frequently multiple (81,82). Multiple renal cysts occur in up to 76% of patients, and histopathologic examination may show a continuum from simple benign cysts to frank RCC.

Interfamilial variation in predisposition to pheochromocytoma is well recognized, such that in some families pheochromocytoma is the most frequent complication but is rare in other families (80,83,84). Patients with familial or bilateral pheochromocytoma but no evidence of VHL disease may have germline VHL gene mutations, and in such cases careful investigation for subclinical evidence of VHL disease and for VHL gene mutations is indicated. Genotype–phenotype correlations have revealed that the incidence of pheochromocytoma is higher in families with missense mutations

than in those with large germline deletions or mutations predicted to produce a truncated protein product, and VHL disease families may be categorized according to the presence or absence of pheochromocytoma (types 2 and type 1, respectively). Most type 2 families are further subclassified as type 2B (pheochromocytoma plus hemangioblastomas and RCC), but type 2A (pheochromocytoma and hemangioblastomas but no RCC) and type 2C (pheochromocytoma only) kindreds are also distinguished.

Pancreatic cysts are frequent, and pancreatic tumors, usually nonfunctional islet cell, occur in approximately 5–10% of patients. Pancreatic tumors may become malignant, and detailed guidelines on the management of pancreatic tumors are available (85).

Endolymphatic sac tumors (ELST) are a recently recognized complication of VHL disease that can be detected (by MRI) in up to 11% of cases (86). Impaired hearing, tinnitus, or vertigo in a VHL patient should lead to investigations for an ELST.

When there is a family history of VHL disease a diagnosis can be made in the presence of a single hemangioblastoma or visceral tumor (e.g. pheochromocytoma or RCC). In isolated cases a clinical diagnosis requires two or more hemangioblastomas (retinal or central nervous system) or a single hemangioblastoma in association with a visceral tumor, but molecular genetic analysis provides an alternative method of diagnosis in patients who do not satisfy conventional diagnostic criteria. Germline VHL gene mutations have been reported in approximately 50% of patients with familial or bilateral pheochromocytoma and 4% of patients with isolated cerebellar haemangioblastoma and no clinical or radiological evidence of VHL disease (Jes et al., 2000,

**FIGURE 66-1** von Hippel–Lindau disease. Age-dependent probability of developing retinal hemangioblastoma (RET), cerebellar hemangioblastoma (CHB), and renal cell carcinoma (RCC). From Maher, E. R.; Yates, J. R. W.; Harries, R., et al. *Clinical Features and Natural History of von Hippel–Lindau Disease*. Q. J. Med. **1990**, 77, 1151–1163.

(87)). VHL gene mutation analysis is also indicated in isolated retinal hemangioblastoma and familial clear cell RCC.

Early detection and treatment of complications reduces morbidity and mortality from VHL disease, and all affected patients and at-risk relatives should be entered into a systematic screening protocol such as that described in Table 66-1. Increasingly the efficiency of screening protocols is enhanced by molecular genetic diagnosis, such that screening is confined to proven gene carriers. Relatives who have not inherited a VHL mutation are then spared unnecessary surveillance. Peripheral retinal hemangioblastoma can usually be treated by laser photocoagulation or cryosurgery though the treatment of optic disk lesions is more difficult because of the risk of laser-induced optic nerve damage. Cerebellar hemangioblastomas are benign tumors, and small asymptomatic tumors usually do not require treatment. Surgical removal of cerebellar hemisphere lesions usually produces a good result, but the treatment of spinal and brainstem hemangioblastomas is difficult, particularly in the presence of multiple tumors. Stereotactic radiotherapy may occasionally be used for small tumors when surgery is not possible. RCC is the leading cause of death in VHL disease, but early detection of renal tumors by ultrasound or MRI allows small localized renal tumors to be removed. Most centers employ a conservative renal-sparing approach to the management of RCC in VHL disease, with local excision of the tumor

or partial nephrectomy (88). Asymptomatic tumors are followed until they reach 3 cm, and then surgery is performed. At this time additional smaller tumors may also be removed (89). Although there is a high risk of developing further primary tumors, the aim is to preserve renal function. With repeater surgery, treatment for end-stage renal failure may become necessary, and although relatively few VHL patients have undergone renal transplantation, the morbidity and mortality of renal transplantation appear to be similar to those of non-VHL cases (90).

The VHL tumor suppressor gene was isolated from chromosome 3p25, and germline mutations may be detected in up to 100% of cases (91). Approximately 40% of patients have germline deletions, and the remainder are mainly truncating or missense mutations. Most germline VHL mutations occur rarely and recurrent mutations are relatively uncommon, but genotype–phenotype correlations have been established such that patients with germline deletions, truncating mutations or missense mutation predicted to compromise protein stability usually have a type 1 phenotype without pheochromocytoma. Conversely, surface missense mutations predominate in type 2 (pheochromocytoma present) kindreds (92–94). Specific missense mutations are associated with type 2 phenotype subtypes (2A, 2B and 2C) so that characterization of a germline VHL gene mutation not only allows accurate presymptomatic diagnosis but also can indicate the risk of pheochromocytoma and other tumors.

The mechanism of tumorigenesis in VHL disease is analogous to that in bilateral retinoblastoma, so that tumorigenesis requires inactivation of the wild-type allele (95). In addition, somatic most sporadic clear cell renal carcinomas demonstrate somatic VHL gene mutation, methylation or loss, resulting in homozygous VHL gene inactivation (96–98) consistent with the VHL gene having a critical RCC tumor suppressor function. The VHL tumor suppressor gene has multiple functions (99) but the best characterized is the regulation of hypoxia gene response pathways through its role in a ubiquitin ligase complex. Thus inactivation of VHL leads to upregulation of HIF-1 and HIF-2 (transcription factors that activate transcription of VEGF and other mRNAs in response to hypoxia) because of failure of VHL to target HIF-1 $\alpha$  and HIF-2 $\alpha$  subunits for proteolysis (100). Stabilization of HIF-1 and HIF-2 activates the hypoxic gene response that consists of a large repertoire of target genes implicated in diverse processes such as angiogenesis, proliferation, apoptosis and metabolism (e.g. VEGF, PDGF $\beta$ , TGF $\alpha$ , Cyclin D1 etc) (101), and HIF target genes are thought to have a key role in promoting the angiogenic phenotype characteristic of VHL disease tumors and HIF-2 targets directly promote cell proliferation—so providing a basis for the use of tyrosine kinase inhibitors in metastatic clear cell kidney cancers and, in some cases where surgery is not possible, VHL disease.

**TABLE 66-1** Example Surveillance Program for von Hippel–Lindau Disease

**Affected Patient**

1. Annual physical examination and urine testing
2. Annual direct and indirect ophthalmoscopy
3. MRI brain scan every 3 years up to the age of 50 years and every 5 years thereafter
4. Annual abdominal MRI scan (ultrasound if not available, but CT scan may be required if multiple cysts renal or pancreatic cysts are present)
5. Annual 24-h urine collection for catecholamines and VMAs

**At-Risk Relative**

1. Annual physical examination and urine testing
2. Annual direct and indirect ophthalmoscopy from age 3 to 60 years (fluorescein angiography or angiography may be used from age 10 to increase sensitivity)
3. MRI brain scan every 3 years from age 15 to 40 years and then every 5 years until age 60 years
4. Annual abdominal MRI scan (or ultrasound scan) from age 15 to 65 years<sup>a</sup>
5. Annual 24-h urine collection for catecholamines and VMAs from age 11<sup>a</sup>

MRI, magnetic resonance imaging; CT, computed tomography; VMA, vanillyl-mandelic acid.

<sup>a</sup>Screening for pheochromocytoma can be commenced earlier if there is a family history of pheochromocytoma or a mutation known to be associated with type 2 VHL disease.

**66.1.2.2 Familial Non-von Hippel–Lindau Renal Cell Carcinoma.** By 1991 the literature contained 23 reports of 105 patients with familial RCC and no clinical features of VHL disease (80). Among this group of patients there was an early age at onset (mean 48 years, similar to that in VHL disease and 15 years younger than in nonfamilial cases) (81,102) and evidence for autosomal dominant inheritance with age-dependent penetrance. Since then, the etiology of familial RCC has been clarified by the identification of RCC susceptibility genes and the realization that many genetic disorders are associated with specific RCC histopathological subtypes. Thus 80% of sporadic RCC have a clear cell appearance, and papillary (chromophilic) tumors are the most common cause of non-clear cell RCC. Familial clear cell RCC is associated with VHL disease, non-VHL familial clear cell RCC, and chromosome 3 translocations and a variety of disorders can cause inherited non-clear cell tumors.

FCRC is characterized by two or more relatives with clear cell RCC and no evidence of VHL disease. Convincing evidence for FCRC was provided by Teh and colleagues (103), who described two large kindreds with dominantly inherited clear cell RCC unlinked to the VHL locus. Although most cases of FCRC observed by Teh and colleagues (103) were diagnosed after age 50, Woodward and colleagues (104) reported FCRC kindreds with early-onset RCC and suggested that at-risk relatives should be screened by annual ultrasound from age 20. Extrarenal cancers do not appear to be a frequent feature of FCRC. The genetic basis for most cases of FCRC has not been elucidated, although some may harbor a constitutional translocation or germline VHL, FLCN or SDHB mutations (see later discussion) (105–107).

A constitutional translocation involving chromosome 3 has been reported in a number of families with inherited clear cell RCC. In a large kindred with familial RCC, originally reported by Cohen et al. (108), 10 patients in three generations developed RCC and two also developed papillary thyroid carcinoma (56). Within the family a balanced 3;8 translocation with breakpoints at 3p14.2 and 8q24.1 segregated with RCC susceptibility (translocation carriers were estimated to have an 87% risk of developing RCC by 60 years of age). Other chromosome 3 translocation kindreds associated with RCC have been described but the breakpoints in these families are heterogeneous (although mostly pericentromeric), and although in some cases putative tumor suppressor genes (e.g. FHIT, TRC8, NORE1, LSAMP, FBXW7) or fusion transcripts have been identified by breakpoint cloning, in others it has been suggested that RCC susceptibility results from instability of the derivative chromosome 3 (and loss of the derivative chromosome 3 through nondisjunction and subsequent somatic VHL gene mutation (three-hit model of tumorigenesis)) (76,109). Although familial RCC associated with chromosome

3 translocations is rare, cytogenetic analysis should be performed in FCRC and early-onset/multicentric RCC. However, in chromosome 3 translocation carriers without a personal or family history of RCC (and without disruption of known tumor suppressor genes) the risk of RCC appears to be small (110).

**66.1.2.2.1 Hereditary Papillary Renal Carcinoma.** Histopathologically, papillary cancer may be divided into two subtypes. Germline MET mutations are associated with type 1 tumors that are characterized by small basophilic cells with pale cytoplasm and inconspicuous nuclei (111,112) and type 2 papillary RCC susceptibility may be associated with germline FH mutations (113). Susceptibility to type 1 papillary RCC is rare (incidence approximately 0.1 per million) and is inherited as a dominant trait with incomplete penetrance (94,114). MET is a receptor tyrosine kinase and the mutations described in hereditary papillary renal carcinoma (HPRC) occur in the intracellular tyrosine kinase domain and activate MET activation (115) in a manner analogous to similar kinase domain RET mutations in MEN2B. Interestingly, RCC from HPRC cases with MET mutations demonstrate nonrandom duplication of the mutant chromosome 7 (116). Careful investigation of HPRC kindreds frequently identifies asymptomatic RCC in gene carriers and one MET mutation (H112R) had a penetrance of only 30% by age 50.

Homozygous recessive FH mutations cause FH deficiency, whereas heterozygous mutations predispose to cutaneous and uterine leiomyomatosis (fibroids). A subset of patients with hereditary leiomyomatosis develop type 2 papillary or collecting duct histology RCC (113,117,118) so this dominantly inherited condition is called hereditary leiomyomatosis and renal cell cancer (HLRCC) syndrome. Although only a minority of affected individuals develop RCC, the renal cancers are aggressive and should be removed when detected (in contrast to other familial RCC syndromes such as VHL disease and BHD syndrome in which renal tumors are usually managed conservatively until they reach 3 cm diameter). FH is a key component of the tricarboxylic acid cycle (Krebs cycle) and catalyzes the conversion of fumarate to malate. Tumors from HLRCC patients show activation of the hypoxic gene response pathways (as in VHL disease) secondary to accumulation of fumarate (119,120). In addition fumarate has been reported to promote succination and immunostaining for S-(2-succinyl) cysteine has been suggested as a biomarker for FH-deficient tumors (121).

Two inherited RCC syndromes associated with tumors of variable histopathology are the BHD syndrome and RCC associated with mutations in the succinate dehydrogenase subunit genes.

BHD syndrome was initially linked to familial oncocytoma by Toro and coworkers (122). This dominantly inherited disorder is characterized by cutaneous fibrofolliculomas, lipomas, and spontaneous pneumothoraces

and probably colonic polyps and cancers (123). A gene for BHD syndrome was mapped to 17p and a novel tumor suppressor gene (folliculin, FLCN) was characterized (124). A mutation hotspot within a mononucleotide tract in exon 11 accounts for about 50% of mutations. The function of the BHD gene product has not been defined, but there are two naturally occurring animal models: the Nihon rat and canine hereditary renal cystadenocarcinoma (125,126). BHD is associated with an approximately 30% lifetime risk of renal tumor and renal screening (probably from age 20) should be offered to affected patients and at-risk relatives (127). A variety of histopathological tumor types have been described in BHD syndrome, but the most common types are hybrid chromophore/oncocytoma and clear cell RCC.

Succinate dehydrogenase is a heterotetrameric protein located on the inner mitochondrial membrane, and consists of four subunits (A, B, C and D), and has a critical role in cellular energy metabolism through its dual role in the Krebs cycle and as part of the respiratory chain (mitochondrial complex 2). Heterozygous germline mutations in the gene encoding the D subunit (*SDHD*) were initially associated with familial head and neck paragangliomas (HNPGL) and then sporadic and familial pheochromocytoma (128,129). Thereafter germline mutations in the B subunit gene (*SDHB*) were also demonstrated to cause susceptibility to HNPGL and adrenal and extra-adrenal pheochromocytoma (130) and subsequent studies demonstrated that germline *SDHB* and *SDHD* mutations are a major cause of pheochromocytoma and HNPGL susceptibility. Furthermore, germline *SDHB* mutations are associated with a high risk of malignant pheochromocytoma and about 5% of patients with inherited RCC will have a *SDHB* mutation (105). A variety of histological subtypes of RCC may be associated with *SDHB* mutations (and less frequently *SDHD*) and the lifetime risk of RCC in *SDHB* mutation carriers was estimated to be about 15% (131).

### 66.1.3 Renal Angiomyolipoma

Renal angiomyolipoma is the classic renal lesion of tuberous sclerosis, found in approximately 50% of patients (132). Angiomyolipomas complicating tuberous sclerosis are frequently multiple and bilateral, but sporadic cases also occur and these are typically single, have a later age of onset, and have a female preponderance (133). Renal angiomyolipomas are usually asymptomatic, but severe hemorrhage can occur. Although RCC may complicate tuberous sclerosis, the absolute risk is considered to be low (approximately 2–4%) (134). However, patients with tuberous sclerosis who develop RCC are significantly younger than average and further data is required to define the lifetime risk of RCC (135). Renal imaging in tuberous sclerosis is usually performed for the detection and follow-up of angiomyolipomas, but CT is the most

helpful investigation for differentiating angiomyolipomas and renal cancers.

**66.1.3.1 Tumors of the Ureter and Renal Pelvis.** Carcinoma of the renal pelvis accounts for approximately 10% of all malignant renal tumors. Environmental causes include occupational exposure (as for bladder cancer) and prolonged excessive phenacetin ingestion.

Examples of familial ureteric and renal pelvis transitional cell carcinoma are uncommon but transitional carcinoma of the renal pelvis (together with cancer of the bladder and ureter) can be a feature of hereditary non-polyposis colorectal cancer syndrome (HNPCC, Lynch syndrome) (see discussion below). Sijmons and colleagues (136) estimated that the relative risk of developing transitional cell cancer of the ureter or renal pelvis in HNPCC was 14, although the cumulative risk was <3%. Renal medullary carcinoma arises in the renal parenchyma and is usually seen in young patients with sickle trait (137).

## 66.2 BLADDER NEOPLASMS

Carcinoma of the bladder has an incidence of approximately 30 and 10 per 100,000 in males and females, respectively. Most tumors are transitional cell carcinomas, and a notable feature is the propensity of the patients to develop further urothelial tumors. Environmental exposure to chemical carcinogens was first linked to bladder cancer 100 years ago. Occupational exposure to industrial chemicals, including arylamines, is now firmly established as a predisposing factor, but only a minority of patients will have a significant occupational history (138). Other agents associated with bladder cancer include tobacco smoking, chronic infection (bacterial, schistosomiasis), and phenacetin exposure. There has been much on the interaction of genetic and environmental factors in bladder cancer susceptibility. In particular detoxification of some arylamines is mediated by N-acetyltransferase and phenotypic variations in the activity of this enzyme reflect genetic polymorphisms such that “slow” and “fast” acetylator phenotypes can be distinguished. Cartwright and collaborators (139) found a strong association between slow acetylator phenotype in bladder cancer patients with a history of occupational exposure, although weaker associations have been found in patients with no occupational exposure. In a meta-analysis Johns and Houlston (140) detected a modest association (pooled odds ratio 1.31) with slow acetylator status. Similarly in a meta-analysis of polymorphisms in glutathione S-transferases and human diseases, Haddous et al. (141) observed significant associations between bladder cancer and the GSTM1\*0 null allele and GSTP1 polymorphism in smokers.

In epidemiologic studies, family history confers a twofold increase in bladder cancer risk, but it has been unclear whether this is related to genetic influences or shared environment. Evidence for familial transitional

cell carcinoma of the upper and lower urinary tract has been reviewed by Mueller and coworkers (2008). In addition to rare families suggestive of dominant inheritance with incomplete penetrance, patients with germline retinoblastoma mutations may have an increased risk of bladder cancer (142) and bladder cancer risk is increased in HNPCC (Lynch syndrome)—particularly in men with an MSH2 mutation (143). Nevertheless familial clustering of bladder cancer, although uncommon, has been reported (Mueller et al., 2008). Individuals who are at increased risk of bladder cancer can be screened by half-yearly urinalysis and urinary cytology, with cystourethroscopy when these tests are abnormal. Large genome-wide association studies have identified several low-penetrance risk alleles for bladder cancer and confirmed associations for the GSTM1 and NAT2 and interactions with smoking for both loci (144).

### 66.3 CARCINOMA OF THE PROSTATE

Prostate cancer is the most common cancer and the second cause of cancer death in North American men. Although the etiology is unknown, environmental factors such as a high-fat diet and androgen stimulation have been implicated, and in recent years the role of genetic factors has come under intense scrutiny. Genetic epidemiology studies in Mormon families by Cannon and colleagues (145) suggested that the inheritability of prostate cancer was greater than that of breast or colorectal cancers. Subsequent case-control studies have provided further evidence of familial clustering: Steinberg and colleagues (146) found that 15% of prostate cancer patients had an affected father or brother, compared with 8% of controls, and Spitz and colleagues (147) found a positive family history of prostate cancer in 13% of affected patients and 6% of controls. Overall the relative risk of prostate cancer in men with an affected first-degree relative is approximately twice that of men with no affected relatives and the relative risk increases with the number of affected relatives (146). Further evidence that the familial clustering of prostate cancer was caused by genetic factors rather than shared environment was the observation of Carter and associates (148) that there is a greater risk of familial prostate cancer in early-onset cases and complex segregation analysis suggested that prostate cancer clustering could be caused by a rare, highly penetrant dominantly inherited predisposition gene (frequency in the population 0.36%, penetrance 0.88 at age 85 years) (149). Under the most likely genetic model, 43% of early-onset prostate cancers (age <55) would occur in gene carriers, but only 9% of cases, in those under 85. Linkage studies of familial prostate cancer, although initially promising, proved to be more difficult than those for familial breast and colorectal cancer. A locus (HPC1) was mapped to chromosome 1q24-25 but confirmatory studies were inconsistent (150–152). Other susceptibility loci were linked (e.g. autosomal loci

including PCAP 1q32.2-43, CAPB 1p36, HPC2/ELA2 17p11, HPC20 20q13 and an X-linked locus (HPCX Xq27–q28)) (reviewed in (153)). Although mutations in candidate genes for some loci were reported (e.g. RNA-SEL and ELAC2 for HPC1 and HPC2 respectively), the role of variants within these genes in prostate cancer susceptibility appeared complex and the lack of reproducibility of linkage studies in prostate cancer has been considered as evidence of the fact that extensive locus heterogeneity with familial risk was most likely to be attributable to the inheritance of multiple moderate-risk genetic variants. With the advent of genome-wide association studies a large number of susceptibility alleles have been identified (154,155), although it is unclear how these findings might impact clinical practice (156).

Following reports that carriers of BRCA1 and BRCA2 mutations in familial breast/ovary cancer kindreds had an increased risk of prostate cancer, these genes were analyzed as candidate high-penetrance prostate cancer susceptibility genes and it was found that approximately 2% of men with early-onset prostate (<55 years) had a germline BRCA2 mutation (157). In many cases there was no family history of breast or ovarian cancer. A male BRCA2 mutation carrier was estimated to have a 23-fold increased risk of developing prostate cancer by age 55 years and it also appears that male BRCA2 carriers with prostate cancer have a poorer prognosis than similar noncarriers (158). An increased risk (16-fold) of prostate cancer has been reported in carriers of an Eastern European Nijmegen breakage syndrome (NBS1) mutation (159).

The recognition of genetic factors in determining prostate cancer susceptibility has led to suggestions that men with a high-risk family history should be offered screening from age 40 (148). Gronberg and colleagues (160) recommended that men with two or more close relatives with prostate cancer should be offered screening by PSA measurements and digital rectal examination from ages 50–70 years (screening could be commenced earlier in selected families with a young onset of prostate cancer). However, it is not yet known if such screening will be effective.

### 66.4 TESTICULAR NEOPLASMS

Testicular cancer is the most frequent malignancy in men between 20 and 40 years of age. Most tumors are of germ cell origin (seminoma, teratoma) but approximately 5–10% are sex cord/stromal tumors (e.g. Leydig and Sertoli cell), and gonadoblastoma contain germ cell and stromal elements. Epidemiologic studies have suggested that gonadal hormone drive is a major factor in the development of germ cell tumors. The most important risk factor is cryptorchidism, and this and other conditions (e.g. orchitis, infertility) are associated with reduced testicular function, which would produce increased gonadotropin drive to the testicles. Testicular

tumors are bilateral in about 4% of patients, which is suggestive of a genetic basis (161) and it is estimated that about 2% of all men with testicular cancer may have a genetic predisposition (161,162). In reviewing reports of familial testicular cancer, Patel and colleagues (161) noted that in 12 pairs of identical twins with testicular cancer the tumors were of the same histological type in 70% of cases but that in other affected relative pairs the histology was mostly different. In a Dutch single-center study, relative risk of testicular cancer was increased 9- to 13-fold in brothers (163) and in an analysis of the Swedish Family-Cancer Database, familial risks were increased to 3.8-fold for fathers, 8.3-fold for brothers, and 3.9-fold for sons (164). Large families with a high incidence of testicular cancer have been described but are rare (165,166) and the majority of families are relative pairs, usually brothers, suggesting that susceptibility may be caused by genes with small or moderate effects. An increased risk of testicular germ cell tumors has been reported in Down syndrome and Klinefelter syndrome (167).

Linkage studies in familial testicular cancer were hampered by the paucity of large multigenerational pedigrees and although candidate gene studies identified the Y chromosome *gr/gr* deletion as causing two- to three-fold increase in risk, this variant occurs in <3% of males (168). In contrast, genome-wide association studies have identified significant associations to a number of loci including KITLG, SPRY4, BAK1, DMRT1, TERT and ATF7IP (169,170). Interestingly these loci can be linked to three pathways: KIT, telomerase regulation and sex determination (167).

Genetic disorders predisposing to testicular tumors can be classified according to the presence or absence of abnormal sexual differentiation. Disorders of sex development (DSD) are defined as conditions of incompleter or disordered genital or gonadal development leading to discordances between genetic sex, gonadal sex and phenotypic sex and are subclassified into (1) sex chromosomal DSD, (2) 46XY DSD and (3) 46XX DSD (171). DSD patients with hypervirilization are not at risk of germ cell tumors and the risk is variable in patients with hypovirilization and gonadal dysgenesis.

Gonadoblastoma occurs in XY gonadal dysgenesis and in patients with the WAGR and Frasier syndromes (see previous discussion). The risk of germ cell tumors in gonadal dysgenesis is associated with the presence of Y chromosome material and, in particular, the presence of Yq material. Girls with Turner syndrome and 45X, 46XX, or 46X, del (X) are not at increased risk of germ cell tumors, but up to 20% of patients with gonadal dysgenesis and 45X/46XY or other karyotypes with Y chromosome material may develop gonadoblastoma (172). Gonadoblastoma usually develops in the second and third decades and may secrete estrogens or testosterone. Deletion mapping in patients with gonadoblastoma and Y chromosome deletions indicated that the genes

on the Y chromosome that induce gonadoblastoma are distinct from the sex-determining locus (173) and the TSPY (testis-specific protein Y-encoded) is thought to be the Y chromosome gonadoblastoma locus (GBY) (174). Although bilateral testicular germ cell tumors have been reported in Klinefelter syndrome (175,176), testicular tumors are not common and most germ cell tumors associated with Klinefelter syndrome have an extragonadal origin (177). The detection of low-level 45X/46XY mosaicism by sensitive molecular analysis in girls with Turner syndrome is helpful in identifying those who are at potential risks for gonadoblastoma (178). There is probably no increased risk of gonadoblastoma in Klinefelter syndrome ((51); XXY) or in the XYY syndrome. However, gonadoblastoma is associated with sex reversal caused by 9p deletion (179).

The association between the presence of a Y chromosome and gonadoblastoma is also a feature of single-gene disorder causes of DSD. XX forms of gonadal dysgenesis are probably not associated with an increased risk for gonadoblastomas, but XY pure gonadal dysgenesis (Swyer's syndrome, which may result from SRY mutations) is frequently complicated by this tumor. Affected individuals are of normal stature and do not have the features of Turner syndrome, but have streak gonads. The incidence of gonadal neoplasia in true hermaphrodites (individuals with both testicular and ovarian tissue) appears to be low, although both ovarian and testicular tumors have been reported. Complete androgen insensitivity syndrome (testicular feminization) is inherited as an X-linked recessive disorder and is associated with an increased risk of testicular malignancy (about 5%), most often seminoma. If malignancy develops it is usually after age 25 so that orchidectomy can be delayed until after the pubertal growth (172). An increased incidence of benign testicular tumors has been reported in congenital adrenal hyperplasia (180). Testicular germ cell tumor has also been reported in a man with familial male-limited precocious puberty secondary to a germline-activating mutation in the luteinizing hormone/chorionic gonadotropin receptor gene (181).

Mendelian disorders not associated with abnormal sexual development that predispose to testicular tumors include Peutz-Jegher syndrome, Carney complex and possibly X-linked ichthyosis. Males with Peutz-Jegher syndrome have an increased risk of testicular tumors, although the risk is less than that of ovarian tumors in affected females. Tumors have been classified as Sertoli cell or sex cord tumors and are usually present with childhood gynecomastia secondary to excess estrogen production (182,183). The Carney complex (synonyms NAME or LAMB syndrome) is a dominantly inherited disorder characterized by patchy skin pigmentation, cardiac myxomas, and endocrine abnormalities. Expression is variable, but Carney and colleagues (184) reported that 56% of affected males had testicular tumors, usually bilateral. Microscopic examination of the tumors

usually reveals a large-cell calcifying Sertoli cell appearance or a Leydig cell tumor. The average age at diagnosis is 17 years (range 5–83), and some patients present with sexual precocity (184). Carney complex is genetically heterogeneous PRKAR1A at 17q22–q24 (Type 1 Carney Complex (CNC1) or at a 2p16 locus (CNC2) (185)). Libé et al. (186) reported that PDE11A sequence variants were associated with the development of large-cell calcifying Sertoli cell tumors (in patients with Carney complex type 1).

Familial Leydig cell tumors with no associated abnormalities were reported in a father and son by Bokemeyer and associates (187). Patients with X-linked ichthyosis (steroid-sulfatase deficiency) have been suggested to be at increased risk of cryptorchidism and testicular tumors (188). Germ cell tumors have been reported in families with Li–Fraumeni syndrome (189), but there is no evidence to suggest that germline p53 mutations are a frequent cause of familial testicular tumors (190).

Individuals at high risk of testicular cancer should be offered appropriate preventive measures. Nonfunctioning testes, which present a significant risk for tumorigenesis (e.g. androgen insensitivity syndrome or XY gonadal dysgenesis), should be removed. Individuals thought to be at high risk of familial testicular tumors can be monitored by regular self-examination and ultrasonography.

## Biography

**Eamonn R Maher** has been professor of Medical Genetics at the University of Birmingham since 1996. A clinician scientist, his research interests relate to identifying the molecular basis of inherited developmental and cancer susceptibility disorders. He has a particular clinical and research interest in the genetics of familial renal tumors and the molecular pathogenesis of sporadic kidney cancer.

## Gastrointestinal Tract and Hepatobiliary Duct System

*E Passarge*

Institut für Humangenetik, Universitätsklinikum Essen, Essen;  
Universitätsklinikum Leipzig, Leipzig, Germany

### ABBREVIATION

HSCR – Hirschsprung Critical Region. Refers to two basic types of this heterogeneous disorder, HSCR type 1 and HSCR type 2 (see text).

### 67.1 INTRODUCTION

The gastrointestinal (GI) tract is composed of the mouth and oral structures, salivary glands, pharynx, esophagus, stomach, small and large intestines, the biliary tract, pancreas, rectum, and anus, and other auxiliary organs that contribute to digestion and adsorption of food. In addition it functions as an organ of immunity. This chapter focuses on gross defects of the intestinal anatomical structures, genetic disorders of the small and the large intestines, and the biliary tract system with emphasis on two genetic disorders, congenital intestinal aganglionosis (Hirschsprung disease) and a complex multisystem disorder affecting the biliary duct system (Alagille syndrome (ALGS)).

GI polyposis, neoplasias involving the GI tract, and inflammatory bowel disease are presented in Chapters 67 and 68. Malformations of the GI tract are common in many chromosomal disorders (Chapter 43). Although the most important examples will be mentioned here, the reader is referred to the chapters on chromosomal disorders.

### 67.2 EMBRYOLOGICAL BACKGROUND

The different types of congenital malformations of the GI tract can best be understood on the basis of the underlying normal embryological development. In brief, the cells forming the gut derive from the endoderm for the inner lining, the mucosa, from the ectoderm for the wall, containing muscles and connective tissue, and from the neural crest for the intramural ganglion cells required for peristalsis (1–3). The early precursors of the gut originate from the

inward migration of cells from a small area on the surface of the blastula. In humans, the GI tract develops between the 5th and 12th week of fetal development from a simple ectodermal tube with a mucosal lining. During development the mucosa develops numerous folds and ridges and small fingerlike outgrowths, the villi, eventually to cover its entire surface (for reviews see References (1–3)).

Beginning at the 7-somite stage (Carnegie stage 10, day 22/23), different segments become apparent: the foregut, the midgut, and the hindgut (1). The rostral portion of the foregut becomes esophagus, stomach, and duodenum, with liver, biliary duct, and pancreas. The stomach rotates clockwise about 90°. The midgut becomes greatly elongated and forms a loop in the umbilicus outside the body cavity in the extraembryonic coelom. Because of the rapid growth of the midgut in relation to the abdominal cavity, the newly formed bowel appears to rotate in a counterclockwise direction (Carnegie stage 20, 18–22 mm crown-rump length, day 51–53). The gut is permanently positioned in the abdominal cavity after this 35-mm stage (10th week) (1).

The hindgut is formed by the secondary yolk sac and gives rise to the left third of the transverse colon, the descending and pelvic colons, the rectum and the upper part of the anal canal.

The liver develops during the early stages of duodenum formation (14-somite stage, Carnegie stage 11, day 24), followed by the bile duct system. The bile capillaries are produced by canalization of the minor intrahepatic divisions of the hepatic trabeculae. The pancreas develops from a structure that first reaches the mesenterium (ventral pancreas) and then follows the rotation of the stomach. The bile ducts and the pancreatic duct form a common duct that enters the duodenum.

The abdominal cavity and the pleural cavity become separated by development of the diaphragm. First a septum transversum forms above the liver during the 4th week of fetal development (Carnegie stage 13, 4- to

6-mm embryo, day 28–32). Then a pleuroperitoneal fold originating from the dorsal wall of the cavity extends to and fuses with the septum transversum to complete the diaphragm.

## 67.3 CLASSIFICATION OF GASTROINTESTINAL DISORDERS

Based on the embryological considerations GI disorders can be classified into (1) gross defects of the anatomical structures, (2) disorders resulting from failure of the intramural intestinal ganglion cells to migrate to the gut and establish function there (congenital intestinal aganglionosis, Hirschsprung disease), (3) disorders mainly due to malfunction or malformation of the hepatobiliary system, and (4) functional disorders. For additional information the reader is referred to other reviews (4,5), in particular to McKusick's classification of the Mendelian Inheritance of Man (MIM) (6) and its online version OMIM [www.ncbi.nlm.nih.gov/Omim]. For all such disorders mentioned in this chapter, the OMIM number is provided for easy access to additional information.

### 67.3.1 Gross Defects of the Intestinal Anatomical Structures

Various embryological malfunctions may result in failure of the gut to become fully patent (atresia), failure of the gut to rotate normally (malrotation), duplication of parts of the gut, disruption of the abdominal wall and umbilical structures (gastroschisis and omphalocele), defects of the diaphragm, and anorectal malformations (1–5).

**67.3.1.1 Atresias.** With normal development of the intestines in the human embryo, the proliferating mucosa closes the lumen of the gut during Carnegie stage 17 (11- to 14-mm stage, day 42–44 at the beginning of the 7th week). Subsequently the gut is recanalized and assumes its typical mucosal relief. Failure to recanalize will result in stenosis or atresia of the bowel for various extents at different locations.

*Atresia of the esophagus* (OMIM 189960) with or without a concomitant fistula to the trachea is a prominent cause of neonatal regurgitation and aspiration pneumonia. Its frequency can be estimated at about 1 in 3000 newborns. It may be nonsyndromic as an isolated anatomical defect or syndromic as part of a systemic malformation syndrome (see VATER complex, below). As a nonsyndromic malformation, esophageal atresia with or without tracheal fistula accounts for about one-third of patients with GI atresia. OMIM lists seven reports of familial occurrence, most of them in a child and a parent. However, in most cases atresia of the esophagus does not appear to result from genetic causes that establish an increased risk of recurrence in sibs or offspring of a patient. Most of these observations

occurred with systemic genetic disorders in which esophageal atresia was only one of several or many possible manifestations. It is unlikely that monogenic inheritance plays a role. A very low risk of recurrence can be given in genetic counseling. An interstitial deletion of chromosome 17 [del(17)(q22q23.3)] has been reported to be associated with esophageal atresia (7).

*Duodenal atresia* (OMIM 223400) accounts for about 10 % of atresias at a frequency of about 1 in 5000 newborns. OMIM lists five reports of familial occurrence, but in most cases a genetic origin is unlikely. Duodenal atresia is a characteristic concomitant malformation of trisomy 21 (8,9).

*Jejunal atresia* (OMIM 243600) occurs in about 1 in 4000 newborns, making the jejunum the most common site of bowel obstruction in the newborn. Although seven observations of familial occurrence have been reported in OMIM, a genetic cause appears to be uncommon. In the absence of a previously observed patient in the same family, a low risk of recurrence can be given in genetic counseling.

Multiple intestinal atresias (familial intestinal polyatresia syndrome or apple peel syndrome) may represent a distinct subtype. It has been reported in sibs and in an inbred kindred (see OMIM 243150). However, a monogenic cause is unlikely to account for most of these cases.

Five different anatomical types of jejunal obstruction have been distinguished (10,116): type I (mucosal web), type II (ends separated by a fibrous cord), type IIIa (ends separated by a V-shaped mesenteric defect), type IIIb (“apple peel” deformity), and type IV (multiple atresias). Type IIIb most commonly shows familial occurrence, although familial cases of types I, II, and IV have also been observed (see OMIM 243150).

*Anal atresia or imperforate anus* (OMIM 207500) occurs in about 1 per 5000 births. Although it has been observed in sibs (MIM 207500 and 301800), genetic factors probably contribute little to the etiology. For most isolated cases a low risk of recurrence can be assumed. However, in more than half of the patients, anal atresia occurs together with other malformations as one component of a Mendelian, chromosomal, or nongenetic syndrome. OMIM lists 20 entries under the heading *anal atresia*. Pinsky (11) listed 26 different disorders involving anorectal malformations.

Anal atresia is a frequent component of the VATER complex (MIM 192350). This is an acronym for vertebral, anal, tracheoesophageal, renal and radial limb malformations. Cardiovascular and nonradial limb malformations may also be present (VACTERL, OMIM 276950, 314390). This nongenetic malformation complex rarely includes all components in an individual patient. Usually, only a few of the malformations are manifest (8).

Anal atresia is a feature of the cat-eye syndrome (OMIM 115470), a chromosomal disorder resulting from an inverted duplication of 22q11, which leads

to tetrasomy of this region (the CES critical region, see chapter on chromosomal disorders). The cat-eye syndrome shows wide phenotypic variability, ranging from near normal to ones with severe malformations (12). Preauricular skin tags and/or pits constituted the most consistent features.

Anorectal malformations (imperforate anus and anal stenosis) are a hallmark of the autosomal dominant *Townes–Brock syndrome* (OMIM 107480) (10,13,14). Other variable manifestations are anomalies of the hands (preaxial polydactyly, triphalangeal thumbs, hypoplastic thumbs) and feet (syndactyly III/IV, short metatarsals, and overlapping toes), sensorineural deafness and malformed auricles, dysplastic kidneys, hypospadias, cardiac malformations (not only atrial and ventricular septal defects but also lethal truncus arteriosus in one case and pulmonary valve atresia in another), mental retardation, and other manifestations. This disorder results from mutations in the *SALL1* zinc finger transcription factor gene located on 16q12.1 (10,13,14). *SALL1* (OMIM 602218) is the human homolog of the *spalt* gene (*Sal*) in *Drosophila melanogaster*, a developmental regulator that is conserved throughout evolution. The expression patterns of *sal*-like genes in mouse, *Xenopus*, and the fish Medaka suggest that *sal* is regulated by sonic hedgehog (*SHH*; OMIM 600725).

Anal atresia or stenosis may be a feature of the CHARGE syndrome (Coloboma-Heart defect-Choanal atresia-Retardation-Genital and Ear Anomalies, OMIM 214800). Most cases are sporadic. However, rare familial occurrence, a high rate of concordance in monozygotic twins, and mutations in two genes (*CHD7* at 8q12.1 and *SEMA3E* at 7q21.11) suggest that genetic causes can occur.

**67.3.1.2 Defects of the Abdominal Wall.** *Gastroschisis* (OMIM 230750) is a disruption of the abdominal wall outside the umbilicus because of diverse causes. With a frequency of 1–2 per 10,000 births it represents a relatively common anatomical defect in the newborn (17). OMIM lists six entries for gastroschisis (230750), omphalocele (164750), constrictive bands (217100), and a mouse homolog called disorganization (223200). In most cases gastroschisis does not seem to result from a genetic cause, but exceptional occurrence in sibs has been reported (see OMIM 230750). Gastroschisis has been found to occur in 14.1% (469 of 3322) cases worldwide as part of manifestation of other disorders or multiple congenital anomalies (15). Other additional risk factors have been considered (16).

In a population-based registry, Torfs and Curry (15) found six other family members with this defect among 127 infants with gastroschisis, corresponding to a possible recurrence rate of 3.5%. Other observations, in particular of discordance in monozygous twins and absence of recurrence in 44 families (16–18), do not point to a genetic etiology. An abdominal wall defect may also be part of an amniotic band disruption

complex. An analysis of 274 cases of gastroschisis (79% isolated) in 21 regional registers in Europe (EUROCAT registers) during the period 1980–1990 indicated a prevalence rate of 0.94 per 10,000 (19,20). Gastroschisis can be recognized by ultrasonographic prenatal diagnosis. A gene–environmental model involving the VEG-NOS3 pathway has been invoked (21).

*Omphalocele* (OMIM 164750) is a defect of the abdominal wall at the base of an umbilical ring that has remained open and contains part of the intestines, occasionally of considerable extent. Although there have been three reports of isolated omphalocele in sibs (see OMIM 164750), a genetic etiology is unlikely in most cases. However, omphalocele is an important component of the Beckwith–Wiedemann (OMIM 130650) and the Shprintzen–Goldberg syndromes (OMIM 182210). OMIM lists 37 entries for omphalocele as a part of other systemic disorders.

Kanagawa et al. (22) reported a family with nine individuals in three generations affected with a presumptively autosomal dominant form of omphalocele that required surgical intervention within the first few days of life. Yatsenko et al. (23) observed a patient with omphalocele, dysmorphic features, and mild developmental delay associated with trisomy for region 3q27.3-qter and monosomy for 4q32.3-qter resulting from an unbalanced translocation of maternal origin. The association of a duplication for the long arm of chromosome 3 and an omphalocele has been reported previously in several instances (see OMIM 164750).

Katz et al. (24) suggested that mutations in the *PITX2* gene might contribute to the causes of omphalocele and VATER-like syndromes in some patients. They found a three base pair deletion in the 3′ untranslated region of *PITX2* in one patient with this combination, but neither in patients with isolated omphalocele nor in normal controls.

**67.3.1.3 Malrotation.** Malrotation (OMIM 193250) of variable extent is a common result of the normal embryonic origin of the GI tract. OMIM lists four familial reports, but a genetic basis for malrotation alone is unlikely. It is a frequent component of chromosomal and several monogenic disorders.

**67.3.1.4 Duplication.** Parts of the intestines may be duplicated as a result of unknown embryonic causes. No evidence for primary genetic causes exists.

**67.3.1.5 Meckel Diverticulum.** Meckel diverticulum (OMIM 155140) is a dilated proximal omphalomesenteric duct connected to the distal ileum. It occurs in 1–2 % of newborns, often without clinical consequences. Although familial occurrence has been reported, there is no evidence for genetic factors in most patients. It may also occur in the cat-eye syndrome (OMIM 115470), Simpson–Golabi–Behmel syndrome type 1 (OMIM 312870), Beckwith–Wiedemann syndrome (OMIM 130650), and Pena–Shoheir syndrome type 1 (OMIM 208150).

**67.3.1.6 Partial Agenesis of the Pancreas.** Agenesis of the dorsal pancreas (OMIM 167755) has been reported

in a mother and her two sons of different fathers (25). However, this appears to be a rare defect without a known genetic basis.

Yorifuji et al. (26) described hypoplasia of the pancreas in a mother and three of her offspring in a nonconsanguineous Japanese family (OMIM 600001). In addition, atrial septal defect (MIM 607411) and patent ductus arteriosus were present in the mother, whereas severe cardiac malformations (transposition of the great vessels, ventricular septal defects, pulmonic stenosis, atrial septal defect, and tetralogy of Fallot) were documented in her children.

Congenital agenesis of the pancreas OMIM (260370) has been associated with a gene at 13q12.1 (*PDX1/IPF1*) and the possibility that a mutation in the gene for insulin promoter factor-1 (*IPF1*; 600733) could be responsible. Pancreatic and cerebellar agenesis may be caused by mutation in the *PTF1A* gene (see OMIM 607194).

**67.3.1.7 Defects of the Diaphragm.** Congenital diaphragmatic hernia (CDH) is part of the heterogeneous group of defects in the development of the diaphragm with a prevalence among newborns of 1 in 2500–4000 with a mortality rate of 30–60% due to lethal pulmonary hypoplasia. Two types, DIH1 and DIH2 have been mapped to 15q26.1 and 8p23.1, respectively (OMIM 142340). A third form, DIH3, has been associated with a mutation in the zinc finger gene *ZFPM2* (OMIM 603693). A possible X-linked form exists (OMIM 306950).

For isolated CDH, including congenital absence of the diaphragm, an empirical risk of recurrence of about 3.5% might exist for sibs (26–31). CDH occurs as a syndromic part of the Fryns syndrome (OMIM 229850), Simpson–Golabi–Behmel syndrome (OMIM 312870), tetrasomy 12p (OMIM 601803), Brachmann–de Lange syndrome (OMIM 122470), and lethal multiple pterygium syndrome (OMIM 253250) (30).

## 67.3.2 Congenital Intestinal Aganglionosis (Hirschsprung Disease)

**67.3.2.1 Definition and Clinical Aspects.** Hirschsprung disease (OMIM 142623) is a genetically determined, multigenic, neonatal intestinal obstruction syndrome that is correctable by surgery. It is genetically heterogeneous and clinically variable, ranging from severe in neonates to mild in late infancy and childhood. The main clinical manifestations are chronic constipation, abdominal distension and a megacolon of variable length (Figure 67-1). A neonate may present with meconium ileus and sigmoid perforation; impaired defecation is a leading sign in all cases. The diagnosis is confirmed by rectal biopsy by demonstrating the absence of intramural intestinal ganglion cells. Surgical intervention by removing the aganglionic distended part of the colon is successful in most cases, but early recognition and therapy are important. With a population incidence of 1 in 5000 newborns, Hirschsprung disease is the most common cause of intestinal obstruction in neonates and during early childhood. The sex ratio is approximately four males to one female. Reliable diagnostic criteria, successful surgical intervention in most cases, follow-up management, and genetics have established the scientific basis for good patient care and genetic counseling. Congenital intestinal aganglionosis may be a component of numerous other genetic syndromes (see syndromic forms below).

Hirschsprung disease was first described in 1869 (32), but it became known as a GI pediatric disease entity following the description by Harald Hirschsprung in 1889 in Copenhagen (33). Its pathogenesis, absence of intramural ganglion cells in the myenteric (Auerbach) and submucosal (Meissner) plexuses of the intrinsic GI tract, was recognized in 1948 (34,35). Earlier observations had pointed in this direction, but did not draw the correct conclusions (36,37). The population incidence

**FIGURE 67-1** Hirschsprung disease. (A) Distended abdomen due to megacolon. (B) Infant with severe form of megacolon. (Photo courtesy Dr Lester Martin, Cincinnati.)

in European populations is about 1:5000, with a ratio of affected males to females of 4.5:1. Until the late 1950s, before the introduction of several successful surgical procedures, this disease was almost invariably fatal in infancy or early childhood. Observations of rare familial occurrence in sibs, and later in surviving affected parents, led to systematic genetic studies in the 1960s and 1970s. The era of molecular genetics of Hirschsprung disease began in 1973, when close linkage with the gene *RET* was first demonstrated (38,39). Hirschsprung disease may occur in syndromic form as a component of numerous other genetic disorders (see below). For comprehensive reviews see references (40–43).

**67.3.2.2 Types of Aganglionosis.** The terminal portion of the colon just above the rectum is always involved, but the upper (rostral) border is highly variable. Thus, Hirschsprung disease is classified into two basic types, according to the length of the aganglionic segment: short-segment Hirschsprung disease (also called type I or S-HSCR), occurring in approximately 60–85% of patients and long-segment Hirschsprung disease (type II or L-HSCR), occurring in 15–25%. The short-segment type is defined as aganglionosis below the upper sigmoid and the long-segment type as aganglionosis extending beyond the splenic flexure into the transverse colon, which may also involve part of the ascending colon. In a small proportion of patients (approximately 3–5%), the entire colon and various parts of the small intestine may be aganglionic (total colonic aganglionosis). Other rare variants are total intestinal aganglionosis, ultrashort-segment aganglionosis (from the distal rectum to the normal aganglionic zone 2 cm above the pectinate line), and segmental aganglionosis above a normal distal segment, which is reported in very few cases only (for reviews see References (40,43,44)). About 70% of patients with Hirschsprung disease have no other manifestations, approximately 18% have associated congenital malformations or a different genetic disorder, and approximately 12% have a chromosomal aberration, mostly trisomy 21 (see syndromic forms of Hirschsprung disease below).

#### 67.3.2.3 Formal Genetics.

**67.3.2.3.1 Inheritance Pattern.** Systematic genetic studies of the familial occurrence of nonsyndromic Hirschsprung disease preceded the identification of the genes involved (45–49), and these studies are still a reasonable basis for genetic counseling. The overall risk of occurrence in siblings is approximately 4%, approximately 200 times the population risk. In spite of the existence of pedigrees showing an autosomal dominant or an autosomal recessive mode of inheritance (50), a Mendelian inheritance pattern is absent in the families of most patients. For this reason and based on a detailed analysis, taking the gender of the index patient and affected siblings into account, a multigenic

(multifactorial) model has been invoked to explain the unusual inheritance pattern of Hirschsprung disease. This model assumes that the proportion of disease predisposing alleles is higher in females than in males. Furthermore, the length of the aganglionic segment greatly influences the genetic risk. The longer it is, the higher the risk of recurrence in a first-degree relative (Table 67-1).

Thus, the proportion of affected siblings is higher if the index patient is female (6–18%) than when the index patient is male (0.6–8%), which is the opposite of the sex ratio in the general population with four males to one female (Carter effect). The familial incidence is lower in S-HSCR than in L-HSCR (reviewed in References (40,43,49)).

**67.3.2.3.2 Genetic Counseling.** The risk of an affected sib is high if the index patient is female with a long aganglionic segment and the sib is male (18%), compared with 7% if the aganglionic segment is short. In contrast, female sibs of a male index patient have a low risk of 0.6% for type 1 (short) and 3% for type 2 (Table 67-1). Thus, the risk to sibs is higher if the index patient is female rather than male. This is the opposite of the population incidence, with a ratio of four males affected to one female. This seeming paradox, first described in the 1960s by C.O. Carter for pyloric stenosis (see below), is called the *Carter effect*. It is interpreted as being due to a multigenic population difference between males and females. They differ in a threshold effect: it takes more contributing genetic factors for disease manifestation in females than it does in males, the latter presumably being more liable to the disease than females. The gender of the parent and the length of the aganglionic segment also influences the average risk to

**TABLE 67-1 Empirical Risk for Nonsyndromic Hirschsprung Disease<sup>a</sup>**

Risk to Sibs (%)		
Sex of Index Patient	Male	Female
Male		
Type I (short) <sup>b</sup>	4	1
Type II (long)	11	8
Female		
Type I	6	2
Type II	23	18
Risk to Offspring of an Affected Parent (%)		
Affected Male		
Type I	0.5	0.5
Type II	28	22
Affected Female		
Type I	0.5	0.5
Type II	28	22

<sup>a</sup>Data from Bodian and Carter, (45); Madsen, (46); Passarge, (47), (49), and Chakravarti and Lyonnet, (40).

<sup>b</sup>Length of aganglionic segment defined as type I for absence of intestinal ganglion cells caudal to the splenic flexure, and as type II for absence anywhere further rostral to this point (see text).

offspring of a parent affected with Hirschsprung disease (Table 67-1).

Caution should be exercised when applying the empirically derived risk figures because the actual risk in a given family might come close to that of an autosomal dominant or recessive inheritance pattern. The risk of recurrence depends on the underlying disease if intestinal aganglionosis occurs as a component of a systemic disorder (syndromic Hirschsprung disease, see below).

**67.3.2.4 Diagnosis.** The current low mutation detection rate (up to about 60%) makes a molecular genetic confirmation of the diagnosis of Hirschsprung disease untenable in most cases. However, based on the history and clinical findings, and confirmed by rectal biopsy, a reliable diagnosis can be established without mutation analysis.

**67.3.2.4.1 Clinical Signs.** Failure to pass meconium within the first 48 h is the first and sometimes only manifestation in the neonatal period. Vomiting and abdominal distension occur within the first few weeks in about 20–70% and 30–90%, respectively. Beyond the neonatal period, constipation (in 68%) associated with abdominal distension (in 64%) with vomiting (in 37%) become leading signs. Hirschsprung disease should be considered in unexplained perforation of the caecum or appendix (44).

**67.3.2.4.2 X-Ray.** Regular abdominal X-rays show a distended proximal colon and small intestines above an empty rectum. Barium enema supports the diagnosis in most cases by demonstrating a small rectum with a transition zone between the narrow aganglionic and the dilated proximal colon. Anorectal manometry shows an absence of the normal relaxation of the internal sphincter in response to rectal distension. However, this normal rectoenteric reflex only develops within 2 weeks after birth and cannot be used in the newborn (40).

**67.3.2.4.3 Rectal Biopsy.** The absence of ganglion cells in the myenteric plexus (Auerbach) and the submucosal plexus (Meissner) of the colon over a variable length is the hallmark of Hirschsprung disease. The diagnosis

can be confirmed by full-thickness rectal biopsy or suction rectal biopsy. The former requires general anesthesia and experience in interpretation (40). Suction rectal biopsy can be taken without anesthesia but samples the superficial submucosal plexus only. In many cases this is sufficient to establish the diagnosis by showing either aganglionosis or absence of the regular neural network associated with aganglionosis.

The diagnosis rests on histological and histochemical demonstration of aganglionosis following a rectal biopsy. Since the intrinsic innervation of the anal canal is separated from that of the intestines by a zone above the pectinate line about 10–20 mm that normally does not contain ganglion cells, the rectal biopsy must be taken high enough to ensure diagnostic reliability. Since another zone 4–5 mm rostrally normally has relatively few ganglion cells, a rectal biopsy must be taken 20–30 mm above the pectinate line to reach both the myenteric and the submucosal layers and ensure diagnostic reliability.

#### 67.3.2.5 Molecular Genetics.

**67.3.2.5.1 Genes and Loci Involved.** As of April 2011, mutations at nine known partially interdependent genes are recognized to be involved in causing of Hirschsprung disease (Table 67.2). Autosomal dominant mutations are in the *RET* gene (Rearranged during Transfection protooncogene, OMIM 164761; HSCR1) and in its ligand, the *GDNF* (*glial-cell-derived neurotrophic factor*) gene on 5p13.1–p12 (OMIM 600837; HSCR3). Recessive mutations, observed in an inbred Mennonite population (51) are (1) in the *EDNRB* (*endothelin receptor type B*) gene on 13q22 (OMIM 131244; HSCR2) and its ligand, the *EDN3* (*endothelin-3*) gene on 20q13.2–q13.3 (OMIM 131242; HSCR4), (2) in the *SOX10* [*SRY (sex determining region Y)-box 10*] gene on 22q13 (OMIM 602229), and (3) in three further loci (Table 67-2).

Three different, presumably functionally unrelated signaling pathways are involved in the normal development of the neural-crest-derived intestinal ganglion cells. These are (1) the *RET* receptor tyrosine kinase pathway,

**TABLE 67-2 Genes Involved in the Causes of Hirschsprung Disease<sup>a</sup>**

Gene	Location	Main Effect	Penetrance	OMIM
<i>RET</i>	10q11.2	Dominant, loss of function	50–72%	164761
<i>GDNF</i>	5p13.1	Dominant/recessive	Unknown	600837
<i>EDNRB</i>	13q22	Recessive	8–85%	131244
<i>EDN3</i>	20q13	Recessive	Unknown	131242
<i>SOX10</i>	22q13	Dominant/recessive <sup>b</sup>	>80%	602229
<i>ECE1</i>	1p36	Dominant/recessive <sup>b</sup>	Unknown	600423
<i>NTN, NRTN</i>	19p13	Unknown	Unknown	601880
<i>ZEB2</i> (formerly <i>ZFHX1B, SIP1</i> )	2q22	Sporadic <sup>b</sup>	Unknown	605802
<i>PHOX2B</i>	4p12	Congenital hypoventilation <sup>c</sup>	Unknown	603851

<sup>a</sup>Most genes appear to be interdependent and mutations usually do not segregate in a Mendelian pattern. Data from Chakravarthi and Lyonnet 2001 (40); Passarge, 2011 (43). Predisposing chromosomal regions have been identified at 3p12, 9q31, 16q23, and 19q12 (see text).

<sup>b</sup>Syndromic forms.

<sup>c</sup>Sometimes associated with Hirschsprung disease.

consisting of the genes encoding the RET receptor and its ligand, glial-cell-line-derived neurotrophic factor (GDNF); (2) the endothelin type B receptor pathway, with the EDNRB receptor and its ligand, endothelin-3 (EDN3); and (3) the transcription factor SOX10 (41).

In addition to these genes, susceptibility loci have been identified at 3p12 (HSCR5), 4q31–q32 (HSCR9; OMIM 611644), 9p31 (HSCR6; OMIM 606874), 16q23 (HSCR8; OMIM 608462), and 19q12 (HSCR7; OMIM 606875).

All mutations have a reduced penetrance and variable expression with respect to the length of the aganglionic segment. Dominant mutations at the *RET* locus account for approximately 50% familial patients with Hirschsprung disease and approximately 35% of isolated patients, with a penetrance of 50–70%. Mutations at the *EDNRB* locus on 13q22 are recessive, each with reduced penetrance (30–85%). Mutations in *SOX10* have been found in a syndromic form, the Waardenburg–Shah syndrome (OMIM 277580), associated with Hirschsprung disease. In addition to the genes mentioned above, several modifier genes are thought to influence penetrance and expression of the different causative mutations. Mutations in the *endothelin converting enzyme 1 gene* (*ECE1*; OMIM 600423) seem to be very rare.

**67.3.2.5.2 Role of the RET Gene.** The *RET* gene (MIM 164761), located on the long arm of chromosome 10, region 1, band 1.2, plays a pivotal role in Hirschsprung disease. *RET* was originally described as a protooncogene (*RET* being a term used when this gene was discovered in a different context). Inactivating *RET* mutations are dominant and result in aganglionosis of different types with a penetrance of 50–70% (40,41,43,52–60).

They may occur as a new mutation or are transmitted from a parent. They account for about 50% of familial patients with Hirschsprung disease and about 35% of isolated patients. In short-segment type 1, mutations in the *RET* gene are found in 32%; in long-segment type 2, in 57% (40,41). In addition, changes in noncoding regions of *RET* contribute to the causes of Hirschsprung disease (see below).

The human *RET* gene, located on the long arm of chromosome 10, region 1, band 1.1 (10q11.1; OMIM 164761), encodes a cell surface molecule, receptor tyrosine kinase, expressed in derivatives of the neural crest and neuroectoderm, with functions in development and differentiation of neural crest cell lineages, from which the intramural intestinal ganglion cells also derive (40,41,61). The gene has 21 exons encompassing about 55kb of genomic DNA. Its transcript is alternatively spliced.

The RET receptor is a transmembrane protein of 1114 amino acids with different functionally distinct domains: a signal peptide; three extracellular domains, consisting of the putative ligand-binding domain, a cadherin-like domain, and a cysteine-rich domain; a transmembrane domain; and an intracellular catalytic

domain (Figure 67-2). The last domain is conserved in evolution and is similar to other growth factor receptors. Different mutations in the *RET* gene lead to five clinically different disorders: Hirschsprung disease, multiple endocrine neoplasia type IIA (MEN2A; OMIM 171400), multiple endocrine neoplasia type IIB (MEN2B; OMIM 162300), familial medullary thyroid carcinoma (MTC; OMIM 155240) and pheochromocytoma (OMIM 171300). In a syndromic form associated with congenital hypoventilation (OMIM 603851) mutations in the *PHOX2B* gene (paired-like homeobox 2B; OMIM 603851) have been observed (62).

Over 89 distinct *RET* mutations in Hirschsprung disease are distributed throughout the gene (40). In contrast, in MEN2A, mutations cluster in six cysteine residues in exon 10 (four residues) and exon 11 (two residues). In MEN2B, mutations are of one type only (M918T; (59)). Some mutations overlap in Hirschsprung disease and MEN2A. Hirschsprung disease and MEN2A have been observed in the same patient and can segregate in the same family (63). Loss-of-function mutations in *RET* are associated with Hirschsprung disease in a high proportion of patients, whereas the other conditions are associated with gain-of-function mutations. Presumably insufficient expression levels of RET on the surface of neural crest cells as a result of a mutation interfere with normal migration of ganglion cells to the colon or differentiation in situ. The types of mutations in the *RET* gene causing Hirschsprung disease include missense and nonsense mutations, including deletions. GDNF, one of the ligands of RET, is a transforming growth-factor- $\beta$ -related protein of 211 amino acids that can activate *RET* in cultured cells and is strongly expressed in developing murine gut and kidney mesenchyme (40,41). Mutations in the *GDNF* gene alone are rare. Usually other predisposing changes are present such as mutations in *RET* or trisomy 21. Mutations in *EDN3*,

FIGURE 67-2 RET receptor.

*EDNRB* and *SOX10* are found in approximately 10% of patients with Hirschsprung disease.

Aside from *RET*, another gene expressed as a dosage effect is *EDNRB* on 13q22. Homozygotes for a missense mutation (G to T transversion) of a highly conserved tryptophan residue at position 276 (W276C) in the fifth transmembrane domain of this G-protein-coupled receptor have a 74% risk of developing Hirschsprung disease, whereas the risk is 21% in heterozygotes (64).

Some of the syndromic forms of Hirschsprung disease involve other cell types derived from the neural crest, such as precursors of melanocytes for pigment formation in the cranial region in Waardenburg–Shah syndrome or cells destined to function in the sensory components of the acoustic pathway in associated deafness.

In general, the genotypes and phenotypes, i.e. length of the aganglionic segment, in isolated Hirschsprung disease correlate poorly. Bolk et al. (65) and Bolk Gabriel et al. (66) established that *RET*, the major susceptibility gene, interacts in multiplicative model with one of three chromosomal regions at 3p12, 9q31, and 19q12. This is the first complete genetic dissection of a complex disorder (67).

The current, relatively low mutation detection rate (up to approximately 60%) makes a molecular genetic confirmation of the diagnosis of Hirschsprung disease untenable in most cases. However, based on the patient's history and the clinical findings, a reliable diagnosis (confirmed by rectal biopsy) can be established without mutation analysis. The latter, however, is useful for risk assessment in relatives of a patient.

**67.3.2.5.3 Genetic Contributions by Noncoding *RET* Sequences.** In the majority of families no coding-sequence mutations can be found. In isolated patients this proportion is even lower. However, several studies indicate that certain common polymorphic variants in the *RET* gene contribute to disease susceptibility (68–73). Chakravarti and coworkers (73) identified a common noncoding variant with enhancer function in intron 1 of the *RET* gene that was associated with a 10- to 20-fold increase in susceptibility to Hirschsprung disease. Although this common noncoding mutation (*RET*+3) explains only 2.63% and 1.14% in susceptibility in males and females, respectively, it contrasts with 0.1% of the total variance in susceptibility explained by all known coding mutations (73). Remarkably, a striking gender difference in parental transmission was observed: of 53 informative families, the mutant allele arose from mothers in 35 families and from fathers in 18. This is in keeping with the assumption that females with HSCR carry more susceptibility alleles than males. Interestingly, the worldwide allele frequencies of the mutant *RTE*+3 allele was virtually absent in Africa, but was present in 40% in China and Japan and in 25% in Europe. Emison et al. (73) consider strongly the possibility of a yet unidentified selective advantage similar to the high frequency of

hemoglobin disorders in regions with endemic malaria or chemokine receptors in HIV.

**67.3.2.6 Functional and Embryological Considerations.** Intestinal mobility is controlled by three distinct enteric nervous plexuses: the myenteric plexus of Auerbach, between the circular and longitudinal muscle layers of the muscularis propria, and the two plexuses in the submucosal region, the superficial submucosal plexus of Meissner, just beneath the muscularis mucosa, and the deep submucosal plexus of Henle. Intramural intestinal ganglion cells reach the alimentary tract by migrating from the cephalic neural crest between the 6th and 12th weeks of embryogenesis. This occurs in a defined time sequence with a cranial–caudal gradient (74–77). At 5 weeks' gestation, paired vagal fibers extend to the upper esophagus, but ganglion cells are still absent. At 6 weeks, neuroblasts are present in the esophagus outside the circular layer and the stomach. At 8 weeks (18-mm embryo), ganglion cells are present in the small intestine and the rectum, but not in the colon. At 12 weeks (70 mm) the entire plexus is innervated, presumably by further caudal ganglion cell migration. The most critical period seems to be between weeks 8 and 12, when most of the distal plexus develops.

The neuroblasts that first reach the alimentary tract form the myenteric plexus. The submucosal plexus is formed by neuroblasts migrating from the myenteric plexus across the circular muscle layer into the submucosa (76). The submucosal plexus is also formed in the caudal direction, but later, during the 3rd and 4th months of gestation. The outer longitudinal muscle layer develops from embryonic mesenchymal tissue after the myenteric plexus is formed during the 12th week (76). In contrast to the apparently direct role of vagal nerve fibers, sympathetic and pelvic parasympathetic nerves are not involved in the development of the intramural plexus.

The precursor cells of the intramural intestinal ganglion cells are derived from the neural crest. From here they migrate to the intestines and differentiate into the normal neuronal network, all phases under the control of different genes. For example, sufficient levels of *RET* expression on the surface of the cells involved are thought to be required for migration and differentiation. The failure of the intestinal ganglion cells to migrate from the neural crest or to proliferate, differentiate and survive in the intestinal wall results from several genetic causes, jointly called a neurocristopathy (78). Since other cell types also are derived from the neural crest, the syndromic co-occurrence of Hirschsprung disease with other neurocristopathy syndromes, becomes understandable. These other cells are sensory ganglia, sympathetic neurons, parasympathetic neurons of the autonomous nervous system, endocrine and paraendocrine cells (thyroid C-cells, adrenal medulla, carotid cells), pigment cells and craniofacial mesectoderm (for review, see References (40,117)).

**67.3.2.7 Syndromic Forms of Hirschsprung Disease.**

In approximately 12% of patients with Hirschsprung disease, an associated genetic syndrome is present (see Table 67-3), which often involves another cell lineage derived from the neural crest. In other syndromes, the origin of the association is less clear. The OMIM database lists 50 entries under the heading “Hirschsprung disease.” The most important monogenic disorders associated with Hirschsprung disease are Waardenburg syndrome type I (OMIM 193500) and type IIA (OMIM 193510), Waardenburg–Shah syndrome (OMIM 277580), cartilage–hair hypoplasia (OMIM 250250), Smith–Lemli–Opitz syndrome (OMIM 270400), congenital central hypoventilation syndrome (“congenital Ondine curse”; OMIM 209880), MEN2A (OMIM 171400) and MEN2B (OMIM 162300) (Table 67-3).

Best understood is the association of Hirschsprung disease with defects in other cells derived from the neural crest such as melanocytes in Waardenburg syndrome and sensory components of the acoustic pathway that lead to an association with deafness. The OMIM database lists 17 entries for deafness and Hirschsprung disease. A striking association between trisomy 21 and Hirschsprung disease has been noted in several studies, for example, up to 2.5% of patients with Hirschsprung disease showed this association, also having Down syndrome (45–49). A genetic modifier locus on 21q22 may be responsible for this frequent association (40).

Other chromosomal aberrations are detectable in approximately 8% of patients with Hirschsprung disease,

for example, interstitial deletions at 2p22, 13q22–q32 and 10q11.2 (40,66,67).

**67.3.2.8 Hirschsprung Disease in Mutant Mice.**

Neural-crest-derived associations of pigmentary anomalies and Hirschsprung disease occur in several different mutations in mice, including the recessive coat color mutations piebald, piebald-lethal and lethal-spotting (79–81). Mice homozygous for piebald-lethal and lethal-spotting also have aganglionosis. Approximately 10% of homozygous piebald and piebald–piebald-lethal compound heterozygotes have aganglionosis. These data indicate that mutations in different genes differ in penetrance. Perhaps the effect of mutations in the various genes involved in migration, differentiation and network formation of the intramural GI ganglion cells lies in a gene dosage gradient that eventually determines penetrance and expression. Overo-spotted horses, the lethal white foal syndrome with aganglionic megacolon, may be an equestrian model of human Hirschsprung disease (82).

Mice carrying mutations in the *Ret* gene pathway differ from humans in three aspects: (1) occurrence of aganglionosis only in homozygous null genotypes for *Ret* and *Gdnf*, (2) complete penetrance in most mice, and (3) absence of sex bias, in contrast to a two-fold higher penetrance in human males compared to females (41). On the other hand, penetrance of the phenotype of *Ret*<sup>+/−</sup>;*Ednrb*<sup>sls</sup> mice is greater in males than in females as it is in humans. This indicates that mutant alleles at the mouse genes *Ret* and *Ednrb* might interact as a cause of aganglionosis (41). If confirmed, this would be evidence of an interaction between two genes in two different signaling pathways.

**TABLE 67-3 Syndromic Forms of Hirschsprung disease<sup>a</sup>**

Disorder	OMIM
Multiple endocrine neoplasia type 2A	171400
Multiple endocrine neoplasia type 2B	162300
Familial medullary thyroid carcinoma	155240
Pheochromocytoma	171300
Waardenburg syndrome types 1 and 2	193500/10
Shah–Waardenburg syndrome	277580
Cartilage hair dysplasia	250250
Smith–Lemli–Opitz syndrome	270400
Hypoventilation syndrome	209880
Goldberg–Shprintzen syndrome	609360
Mowat–Wilson syndrome	235730
McKusick–Kaufman syndrome	236700
Polydactyly, renal dysgenesis, and deafness	235740
Brachydactyly type D	306980
Microcephaly and iris coloboma	235730
Dysmorphic facial features and nail hypoplasia	235760
Osteopetrosis, recessive type	259700
Bardet–Biedl syndrome	209900
Piebald trait	172800
Congenital deafness, isolated cases	277580

**67.3.3 Genetic Defects of the Hepatobiliary Duct System**

The hepatobiliary duct system allows drainage of the bile from the biliary glands to the duodenum. Biliary atresia and genetically determined defects of the bile ducts are an important group of syndromic and nonsyndromic disorders.

**67.3.3.1 Biliary Atresia.** Biliary atresia (OMIM 210500) is defined as an infantile disorder characterized by obstructed bile flow due to lack of patent intra- or extrahepatic bile ducts. Often it is part of a systemic genetic disorder. This usually determines the clinical consequences. OMIM lists 17 disorders involving familial occurrence of biliary atresia: extrahepatic biliary atresia (210500), Lambert syndrome (245550, see below), biliary atresia with ichthyosis congenita (242400), multiple intestinal atresias (243150, see jejunal atresia), cat-eye syndrome (115470), biliary malformation with renal tubular insufficiency (210550), multiple GI abnormalities (601346, see below), ALGS (118450, see below), Kabuki syndrome (147920), Meckel syndrome type 1 (249000), Hardikar syndrome (612726), mental retardation type

Buenos Aires (Mutchinik syndrome, OMIM 249630), and others.

Mental retardation type Buenos Aires was originally described in 1972 in two children of consanguineous parents (83). They showed an apparently distinctive syndrome of mental and physical retardation, peculiar facies, and heart and renal malformations. Doerfler and colleagues (84) described two brothers with a similar phenotype. In addition, they determined that the two sib pairs, from Buenos Aires and the Ruhr area of Germany, originated from the same geographic region in Poland (former East Prussia). It could not be established whether they are in fact related. Tonoki and colleagues (85) described a Japanese girl with Mutchinick syndrome, indicating that this phenotype is not geographically or ethnically restricted.

Isolated biliary atresia (210500) is etiologically heterogeneous. A monogenic cause is unlikely in most cases in spite of some familial observations. Four sibs with branchial dysplasia, mental deficiency, club feet, inguinal hernia, and intrahepatic biliary atresia have been reported (MIM 245550). MIM 601346 lists three reports of familial occurrence (in sibs) of extrahepatic biliary ducts, duodenal atresia, hypoplastic pancreas and gallbladder, tracheoesophageal fistula, and hypoplastic intestines. The identity as an independent disorder has not been established.

### 67.3.3.2 Arteriohepatic Dysplasia Syndrome (Alagille Syndrome).

**67.3.3.2.1 Clinical Manifestations.** ALGS (OMIM 118450/601920) is a multisystem developmental disorder with important hepatic manifestations resulting from a paucity or atresia of intrahepatic bile ducts, which leads to cholestasis and liver insufficiency in early childhood (86–102). It progresses to cirrhosis and liver failure in a high proportion of patients. Neonatal jaundice is an early manifestation in many but not all patients (87,88). ALGS is the most common form of familial cholestatic liver disease in childhood with a frequency of about 1:70,000 live births. The hepatic manifestations are documented by liver biopsy showing a paucity of intrahepatic ducts in 80–100% of biopsies, to some extent depending on the age of the patient when the biopsy is taken. Elevated serum bile acids, conjugated bilirubin, alkaline phosphatase, cholesterol, and  $\gamma$ -glutamyl transferase are typical laboratory findings. Two forms, ALGS1 (OMIM 118450) and ALGS2 (OMIM 610205), are distinguished by mutation in different genes (see below).

Although originally described in 1969 and 1973, ALGS became established as a recognizable albeit variable disorder in 1975 (86). A particularly wide spectrum of manifestations has been recognized based on molecular genetic analysis (see below). Other organs that can be involved in a variable manner are the heart, skeleton, eyes, kidney, and the vascular system. In addition, growth retardation occurs in 50–90% of patients. Dysmorphic facial features include a broad forehead and prominent

mandible, giving the face a triangular appearance, bulbous nose, and deep-set eyes (Figure 67-3).

*Congenital cardiac malformations* have been reported in 80–95% of patients, most often as tetralogy of Fallot. Other malformations observed are ventricular and atrial septal defects, aortic stenosis, coarctation of the aorta, and pulmonic valvular and peripheral arterial stenoses. Isolated heart disease has been observed as the only manifestation (87–90). The *eye* is involved in 55–88% of patients. Most common are defects of the anterior chamber of the eye (posterior embryotoxon; Rieger and Axenfeld anomalies) visible by slit lamp examination. Since posterior embryotoxon occurs in 8–15% of the normal population, its presence might be difficult to assess. Pigmentary changes of the retina may be present. Other, rare ophthalmological manifestations include microcornea, keratokonus, cataracts, hypoplasia of the iris, and abnormal optic disks (88). Typical *skeletal manifestations* are vertebral malformations, “butterfly” vertebrae in 22–87%, and decreased interpediculate distances in the lumbar spine (90).

*Minor manifestations* are renal anomalies (solitary or ectopic kidney, cysts, dysplastic kidney, renal arterial stenosis, duplication of the renal pelvis or ureters). Intracranial bleeding may occur in 15% with a high rate of morbidity and mortality. The overall development is delayed and may include mental retardation in about 30%, decreased motor skills, and delayed puberty. Other manifestations are a high-pitched voice, tracheal and bronchial stenoses, jejunal and ileal atresia and stenosis, malrotation, macrocephaly, hypothyroidism, and insulin-dependent diabetes mellitus (88,89).

**67.3.3.2.2 Genetics.** The first descriptions of ALGS were based on familial occurrence consistent with autosomal dominant inheritance, but highly variable expressivity and reduced penetrance. The locus first identified was assigned to chromosome 20 at p12 based on microscopically visible deletions and translocations

FIGURE 67-3 Alagille syndrome.

involving this region (92–94). The gene carrying mutations in individuals with ALGS was also localized to this region in 1997 (95–97).

**67.3.3.2.3 Molecular Genetics.** In about 94% of patients, ALGS is caused by mutations in the gene, Jagged-1 (*JAG1*, OMIM 601920), encoding a cell surface membrane protein. It is a member of a family of ligands for transmembrane receptors that function in signal transduction in the Notch signaling pathway (98). This ligand is called Jagged-1 (*JAG1*) in humans. Its receptor, Notch, was originally identified in *D. melanogaster* and the nematode *Caenorhabditis elegans* in functions relating to cell fate decisions in many different cell types. Four receptors, Notch 1, 2, 3, and 4, occur in mammals. Notch is unique by functioning both in cell–cell interactions and as a highly conserved signal transducing system downstream of ligand binding (98). Thus, mutations in the ligand *JAG1* have pleiotropic effects, involving many different cell types and tissues, which is consistent with a central role of the Notch signaling pathway in cell specification, tissue patterning, and morphogenesis throughout development in vertebrates and invertebrates (94,98).

*JAG1* is a transmembrane protein with a single transmembrane domain, a small intracellular domain, a large extracellular domain consisting of 16 extracellular EGF-like (epidermal growth factor) repeats (40–50 amino acids each), three highly conserved regions named DLS (for ligands Delta and Serrate in *Drosophila* and Lag-2 in *C. elegans*) of 40 amino acids, and a 21-amino-acid signal peptide (Figure 67-4).

The *JAG1* gene has 26 exons spanning 36kb of genomic DNA with 88% homology with the rat gene but 96.7% homology for the coding regions (94,98). Its cDNA (GenBank accession number 4557678) is 6kb in size with a coding region of 3657 nucleotides (101). Mutations in *JAG1* can be detected in about 70% of patients. In about 56–70% they occur de novo. More

than 430 affected individuals have been studied to date (88). The types of mutation identified include 3–7% total gene deletions, 72% truncating nonsense mutations resulting in frameshift, 10% splice-site mutations, and 9% missense mutations (88).

Mutations are manifest in the heterozygous state, which is in agreement with the autosomal dominant mode of inheritance observed in families. However, carriers of a mutation with minimal or no manifestation have been observed. The clinical phenotype is not influenced by the type of mutation, since considerable clinical variability has been observed within families with the same mutation (94–100). Presumably a *JAG1* mutation causes haploinsufficiency either by relative lack of the gene product or because it has to be tightly regulated for this ligand to interact with its receptor (97). ALGS2 is due to mutations in the Notch-2 gene (*NOTCH2*, OMIM 600275).

**67.3.3.2.4 Diagnosis and Genetic Counseling.** In a typical constellation the diagnosis can be made easily on the basis of the main manifestations described above. However, a fair proportion of individuals carrying a mutation in the *JAG1* gene have been shown to manifest a few and mild signs only. Since this has been observed within the same family with the same mutation, a prognosis to be expected cannot readily be determined. This needs to be taken into account if prenatal diagnosis is considered. Cytogenetic fluorescence in situ hybridization using a probe containing *JAG1* will detect a deletion in 3–7% of patients. ALGS is transmitted as an autosomal dominant trait. Up to 70% of mutations are de novo. In the absence of a mutation in the parents of a child with proven mutation, a low risk of recurrence may be assumed. Germline mosaicism has not yet been described in a parent. However, it has been demonstrated in a few individuals without clinical manifestations (94,98,102).

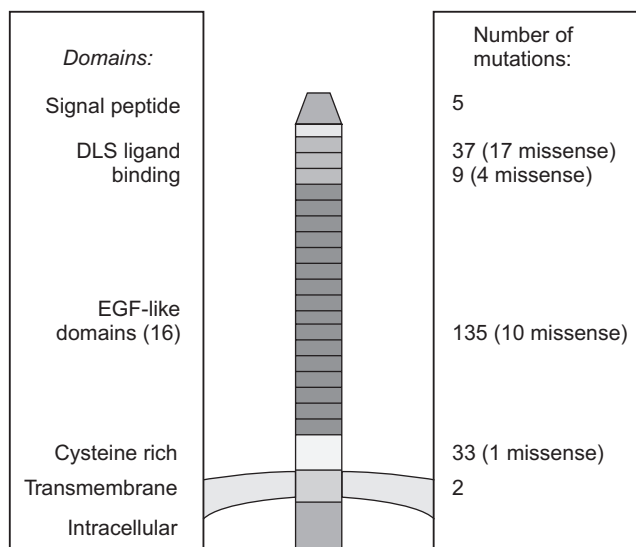

## 67.3.4 Functional Disorders

This is a loosely defined heterogeneous group of disorders. Hereditary pancreatitis, infantile hypertrophic pyloric stenosis (IHPS), achalasia, intestinal pseudo-obstruction, and intussusception are considered here.

**67.3.4.1 Hereditary Pancreatitis.** OMIM (167800) lists 10 reports of familial occurrence under this heading. Four chromosomal regions, 1p36.2, 5q32, 7q31.2 and 7q35, have been identified to be associated with hereditary pancreatitis.

Mutations in the cationic trypsinogen gene *PRSS1* (OMIM 276000) and the gene *SPINK1* (OMIM 167790). This gene encodes a pancreatic secretory trypsin inhibitor. In addition, idiopathic pancreatitis has been found to be associated with mutations in the cystic fibrosis gene (*CFTR*, OMIM 602421).

Audrezet and colleagues analyzed the entire coding sequence and exon/intron junctions of the *PRSS1* (276000), *SPINK1* (167790), and *CFTR* (602421) genes

**FIGURE 67-4** Schematic structure of the Jagged-1 protein.

in 39 white French patients with idiopathic chronic pancreatitis (103). They found a missense mutation (R122H; MIM 276000.0001) in the *PRSS1* gene; 4 patients had the same missense mutation in the *SPINK1* gene, 3 as heterozygotes and 1 as a homozygote (N34S; MIM 167790.0001); and 8 patients carried mutations in the *CFTR* gene.

#### 67.3.4.2 Infantile Hypertrophic Pyloric Stenosis.

OMIM (179010) lists seven entries under the heading IHPS. Five types of IHPS can be distinguished genetically by susceptibility loci on five chromosomal regions: chromosome 12q (IPHS1, OMIM 610260), 16q13-p12 (IPHS2, OMIM 610260), 11q11-q22 (IPHS3, OMIM 612017), Xq23 (IPHS4, OMIM 300711), and 16q24 (IPHS5, OMIM 612525).

IHPS usually manifests at the age of 2–6 weeks of age with projectile vomiting, a palpable pyloric tumor, and gastric peristalsis. It is one of the first and best analyzed examples of multigenic (multifactorial) inheritance in man. From these studies reliable risk figures have been derived, based on the data obtained by the late Cedric O. Carter in the 1960s (104) and summarized by Carter in 1983 in the first edition of this book (105). IHPS is a relatively common component of partial trisomy 9 involving bands q22–31 (106). Only the nonsyndromic type, not associated with other disorders, is considered here.

The incidence of pyloric stenosis in populations of European extraction is about 1.5–3 per 1000 live births (range 0.5–4.5) with an unusual sex ratio of four to five males to one female. Thus, the birth frequency is about 1 in 200–300 males and 1 in 1000–2000 females. The population incidence appears to be lower today than a few decades ago, when the studies by Carter were carried out. In populations of Asian and African origin the incidence is less than in Caucasians, about 1:10,000 and 1:20,000, respectively.

Pyloric stenosis occurs in 2.4–18.9% of first-degree relatives of patients and in 0.5–4.3% of second-degree relatives (Table 67-4), in stark contrast to the population incidence of 0.1–0.5 %. Contrary to what one

might expect, the frequency of affected relatives of female patients is higher than that of male patients. This inverse relationship is also called the Carter effect. It is assumed to result from a threshold for liability to the disease (104–106). The threshold model of a polygenic (or better multigenic) genetic disease assumes that beyond a certain threshold the disease will manifest, below it, it will not. It is the total aggregate of several individually unknown genetic and nongenetic factors that determine that an individual is positioned relative to the threshold. At the population level the distribution resembles a normal Gaussian curve. The patients less frequently affected in the population, in the case of pyloric hypertrophy the females, have a greater genetic contribution than the more frequently affected males. Presumably genetic factors contribute to a lesser degree in males than in females.

According to this threshold model of liability to disease, the highest frequency is in male relatives of female patients (18.9%) and the lowest is in sisters and daughters of male patients (2.4–2.8%), as shown in Table 67-4. As seen in the section on Hirschsprung disease, genetic dissection of multigenic complex disorders aims to identify the individual genes involved.

The gene locus for IHPS type 1 (IPHS1) has been mapped to 12q24.2–24.31. This is based on an altered expression of the neuronal nitric oxide synthase gene (*NOS1*, OMIM 179010) reported in patients with this type of IHPS (107–110). For these studies the investigators used the AAT motif repeat in the first intron of the *NOS1* gene. In a recent study of 16 infants with IHPS and 9 controls, Saur et al. (109) found a significantly decreased expression of *NOS1* mRNA by reverse transcription polymerase chain reaction (RT-PCR). Mutations were found in exon 1c in 3 of the 16 patients. Furthermore, carriers of a single nucleotide polymorphism at position 84 in the exon 1c promoter regions (G84A; OMIM 163731.0001) had an increased risk of developing IHPS. Thus, genetic alterations in the *NOS1* exon 1c regulatory region would appear to influence the expression of this gene and contribute to the pathogenesis of IHPS (109). On the other hand, no linkage between IHPS and *NOS1* was revealed in a study of three Swedish families with multiple affected members (110).

**67.3.4.3 Achalasia.** OMIM (200400) lists five entries under achalasia, which includes several reports of familial occurrence of esophageal achalasia. However, it is doubtful that genetic factors play a role in the etiology in most patients. In a study of 1012 first-degree relatives of 167 patients with achalasia, no other patient has been found (111,112).

**67.3.4.4 Intestinal Pseudo-Obstruction.** Intestinal pseudo-obstruction (OMIM 243180) usually occurs as part of a generalized disorder affecting smooth muscles, autosomal recessive visceral neuropathy. Reports of familial occurrence are listed in OMIM 243180. An autosomal dominant form has been described (OMIM

**TABLE 67-4 Risk of Pyloric Stenosis in Families**

Affected Relatives (%)	Index Patient	
	Male	Female
First-degree		
Brothers	6.5	10.8
Sisters	2.8	3.8
Sons	5.5	18.9
Daughters	2.4	7.0
Second-degree		
Males	2.2	0.5
Females	4.3	1.7
General population	0.5	0.1

Data from Carter (104,105).

609629). Recurrent intestinal pseudo-obstruction may occur in myotonic dystrophy (OMIM 160900).

*Neuronal intestinal dysplasia* (NID; MIM 601223) due to congenital hypoplasia or aplasia of the sympathetic innervation of the intestine may result in intestinal pseudo-obstruction. Two forms of NID are distinguished, NID A and B. NID A is very rare. In NID B a few familial clusters suggest autosomal dominant inheritance.

*Chronic idiopathic intestinal pseudo-obstruction* (CIIP) is caused by a severe abnormality of GI motility, leading to signs of intestinal obstruction without any mechanical lesion (113). It can occur as a manifestation of one of several disorders such as Chagas disease, myxedema, or Duchenne muscular dystrophy. For one form, resulting from qualitative abnormalities of the enteric ganglia and nerve fibers, autosomal recessive inheritance has been suggested. OMIM 243180 lists three familial observations. In general, however, the genetic risk can be considered low.

Auricchio and colleagues described a family with apparent X-linked inheritance (113). They mapped a locus (*CIIPX*) to Xq28. The authors raised the question of whether *CIIPX* may represent an additional susceptibility locus in Hirschsprung disease.

Bott and colleagues described congenital idiopathic intestinal pseudo-obstruction-associated X-linked hydrocephalus with stenosis of the aqueduct of Sylvius (OMIM 307000) in an infant who lacked Cajal cells (114). The patient carried a mutation in the *L1CAM* gene (OMIM 308840.0016) in exon 22, which encodes the fibronectin type III domain of the L1CAM protein. Other mutations of *L1CAM* are involved in Hirschsprung disease, contributing to a quantitative defect in the migration of neural crest cells to distal segments of the gut. Intestinal pseudo-obstruction may occur as part of mitochondrial neurogastrointestinal encephalopathy (OMIM 603041).

**67.3.4.5 Intussusception.** Isolated intussusception (OMIM 147710) is rare, there being only one report of five affected members in three generations of a family. One girl without intussusception had malignant hyperthermia. The authors considered this association fortuitous. Intussusception is an important complication of the Peutz-Jeghers syndrome (OMIM 175200) due to jejunal polyps and in juvenile intestinal polyposis (OMIM 174900).

### Biography

**Eberhard Passarge, MD**, was professor and Founding Chairman of the Department of Human Genetics, University of Essen, Germany, 1976 until mandatory retirement according to Federal University Law in 2001. He was Head of the Division of Cytogenetics and Clinical Genetics at the Department of Human Genetics, University of Hamburg, Germany 1968–1976. Following medical school 1955–1960 he graduated with an MD degree from the University of Freiburg, Germany.

He had postgraduate general medical training at the General Hospital Hamburg-Harburg, Germany, 1961–1962, and The Worcester Memorial Hospital, Worcester, Massachusetts, USA. He received further training in pediatrics and human genetics at the Children's Hospital Medical Center Cincinnati, Ohio, with Josef Warkany 1963–1966 and Cornell Medical Center New York with James German 1966–1968. Among his main interests are the scientific investigation of hereditary and congenital diseases and the application of this knowledge in genetic diagnosis and counseling. He is the author of about 240 articles in international peer-reviewed journals, author of chapters in several international textbooks and three books in human and medical genetics. His experience in teaching human genetics is reflected in his single-author book *Color Atlas of Genetics*, in an upcoming 4th edition. He was Secretary-General of the European Society of Human Genetics (1987–1990) and President of the German Society of Human Genetics (1990–1996), of which he became an honorary member in March 2011. He is a member of the American Society of Human Genetics, founding member of the European Society of Human Genetics, the Teratology Society, and the American Society for the Advancement of Science, corresponding member of the American College of Medical Genetics and other scientific societies. He is married to Mary Fetter Passarge, MD, a graduate of the University of Pennsylvania School of Medicine. Since February 2010 he is the Intermediary Chairman, Department of Human Genetics, University of Leipzig, Germany.

## Inflammatory Bowel Disease

Kent D Taylor, Huiying Yang and Jerome I Rotter

### ABBREVIATION

**ABCB1** – ATP-binding cassette, subfamily B (also known as MDR/TAP), member 1 (ABCB1, Gene Id #5243, OMIM 171050).  
**ANCA** – antineutrophil cytoplasmic antibody.  
**AS** – ankylosing spondylitis.  
**ASCA** – anti-*Saccharomyces cerevisiae* antibody.  
**CARD15** – caspase recruitment domain family, member 15 gene (Gene Id #64127)\*.  
**CD** – Crohn's disease.  
**cM** – centimorgan.  
**DLG5** – discs, large homolog 5 of *Drosophila* gene (Gene Id #9131, OMIM 604090)\*.  
**HLA** – human leukocyte antigen.  
**HLA-DRB1** – major histocompatibility complex, class II, DR beta 1 gene, (Gene Id #3123, OMIM 142857)\*.  
**HPS** – Hermansky–Pudlak syndrome.  
**IBD** – inflammatory bowel disease.  
**ICAM1** – intercellular adhesion molecule 1 (CD54), human rhinovirus receptor (Gene Id #3383, OMIM 147840).  
**IFNG** – interferon, gamma (Gene Id #3458, OMIM 147570)\*.  
**IL** – interleukin.  
**IL1RN** – interleukin 1 receptor antagonist (Gene Id #3557, OMIM 147679).  
**IPAA** – ileal pouch-anal anastomosis.  
**kB** – kilobase pairs (1000 base pairs).  
**LTA** – lymphotoxin alpha (TNF superfamily, member 1) (Gene Id #4049, OMIM 153440)\*.  
**LTB** – lymphotoxin beta (TNF superfamily, member 3) (Gene Id #4050, OMIM 600978)\*.  
**Mb** – megabase pairs (1 million base pairs).  
**MDR1** – see ABCB1.  
**MHC** – major histocompatibility complex, located at 6p21.3.  
**MLOD** – multipoint LOD score.  
**MTHFR** – 5,10-methylenetetrahydrofolate reductase (NADPH) (Gene Id #4524, OMIM 607093)\*.  
**NOD2** – same as CARD15. The mouse gene is named Nod2.  
**NPL** – nonparametric LOD score  
**OMIM** – online Mendelian Inheritance in Man. Online catalog of human genes and genetic disorders edited by Victor A. McKusick, available online from the National Center for Biotechnology Information, National

Institutes of Health, [www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=omim](http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=omim).

**OR** – odds ratio.

**pANCA** – ANCA with perinuclear staining on indirect immunofluorescence.

**PSC** – primary sclerosing cholangitis.

**SCID** – severe combined immunodeficiency.

**SLC11A1** – solute carrier family 11 (proton-coupled divalent metal ion transporters), member 1, also known as natural resistance-associated macrophage protein 1, (Gene Id #6556, OMIM 600266)\*.

**SLC22A4/A5** – solute carrier family 22 (organic cationic transporter), members 4 and 5, also known as OCTN1/2 (SLC22A4 Gene Id #6583, OMIM 604190; SLC22A5 Gene Id #6584, OMIM 603377).

**SNP** – single-nucleotide polymorphism.

**TCR** – T-cell receptor.

**TGF** – transforming growth factor.

**TNF** – tumor necrosis factor (TNF superfamily, member 2) (Gene Id #7124, OMIM 191160)\*.

**TNR** – trinucleotide repeat.

**UC** – ulcerative colitis.

**VNTR** – variable number of tandem repeats.

**95%CI** – 95% confidence interval of the odds ratio.

### 68.1 INTRODUCTION AND DISEASE DEFINITION

The inflammatory bowel diseases (IBDs) consist principally of ulcerative colitis (UC; OMIM#191390) and Crohn's disease (CD; OMIM#266600), two chronic idiopathic inflammatory diseases of the gastrointestinal tract. UC and CD are considered together because of their overlapping clinical, epidemiologic, and pathogenetic features, and shared complications and therapies. CD and UC also present distinct clinical, genetic, and pathologic characteristics as shown in [Table 68-1](#). These similarities and differences suggest that UC and CD may be part of a continuum of IBDs.

The common symptoms in UC and CD are diarrhea, abdominal pain, fever, and weight loss. UC is a chronic inflammation of the colonic and rectal mucosa, characterized by relapses and remissions of rectal bleeding. Inflammation in UC typically begins in the rectum and extends proximally in a continuous pattern without skipping

**TABLE 68-1 Diagnostic Criteria and Clinical Characteristics of Ulcerative Colitis (UC) and Crohn's Disease (CD)**

Method	Ulcerative Colitis	Crohn's Disease
Anatomic location (1)	Colon and rectum only	Any part of the alimentary tract with the most common form ileocolitis
Radiologic	Continuous distribution, fine granularity, fine superficial ulceration, fissures absent, strictures or fistulae rare fissures common, strictures or fistulae common	Discontinuous and segmented distribution, deep ulceration extending into submucosa (transmural), thickening of mucosal folds, luminal narrowing
Endoscopic (2)	Disease almost always involves the rectum and extends proximally for varying distances, inflammation diffuse and continuous, ulceration in inflamed mucosa, normal ileocecal valve, tracts, abscesses, strictures, "cobblestone" appearance	Rectum often spared, asymmetric and skip areas of inflammation, longitudinal ulceration, ileocecal involvement discrete ulcers in normal mucosa, fissures, sinus and fistulous
Histologic	Disease principally involves mucosa; mucosa irregularity, ulceration, increased chronic inflammatory cells in lamina propria. Goblet cell mucin depletion, and glandular dysplasia	Disease is transmural, granulomas, fissures, serositis, and fistulae, granulomas are key, but detectable in only 3% to 50% of CD cases
Extraintestinal (3–5)	Common extraintestinal manifestations include skin manifestations: lesions, arthropathies, ophthalmologic problems (6), disorders in hepatobiliary diseases occur in 21% of UC patients (7)	Frequency (24%) and type of common CD are similar as those in UC (8), thrombotic and thromboembolic vascular complications may occur in CD
Subgroupings	Proctitis, left-sided colitis, pancolitis	Based on anatomic location: ileocolonic, ileitis, jejunoileitis, colonic CD. Based on nature of disease: perforating, nonperforating

areas of the colon. Inflammation is superficial, involving the mucosal/submucosal layers (the inner lining of the gut). In contrast to UC, inflammation in CD may occur anywhere in the gastrointestinal tract, from the mouth to the anus, with both involved and normal segments (skipped) of the intestine observable histologically and endoscopically. The most common form of CD is ileocolitis, affecting both the small bowel and the colon (9). When only the small bowel is affected, CD is also known as *regional ileitis*. In contrast to the superficial inflammation in UC, inflammation in CD is transmural, involving all layers of the bowel wall, mucosa, submucosa, and muscular layer, and sometimes progresses through the bowel wall. The chronic transmural inflammatory nature of CD can result in granulomas, abscesses, fistulae, and perianal complications. There is no etiologic-specific treatment for either form of IBD although colectomy is a curative procedure for UC. Currently, therapy begins with supportive measures and anti-inflammatory agents (e.g. the sulfasalazines and corticosteroids), with the addition of immunosuppressive agents when severe disease does not respond. In our current era, IBD does not increase mortality by itself (10).

Traditionally, the diagnosis of CD and of UC has been based on clinical, radiologic, endoscopic, and histologic findings (reviewed in Table 68-1), but more recently, disease-specific antibodies have been explored for diagnosis (11). Serum antibodies to neutrophils staining with a perinuclear pattern (abbreviated pANCA) and serum anti-*Saccharomyces cerevisiae* antibodies (ASCA) are specific for the IBDs and symptomatic

patients with one of these serologic markers diagnoses UC or CD without further invasive testing although this is not yet general practice. However, because of their relatively low sensitivity, these markers cannot be used as screening tools. In the future, these and other serum antibodies may be useful for classifying individuals with indeterminate colitis. Other serum antibodies will be discussed later.

The main reason for lack of specific treatments for these diseases is our continued poor understanding of the etiology and pathogenesis of the various forms of IBD. On the basis of the current evidence, exogenous or infectious agents, including variation in gut microflora, damage mediated by the immune system, and underlying genetic factors combine to increase susceptibility to disease. Thus, genetic studies are essential for delineating etiologies underlying the continuum of the various forms of IBD. Understanding these etiologies promises to point to cellular and immune pathways that will allow the subsequent development of radically new and specific therapies for these disorders. This understanding will also eventually target those at high risk for disease prevention.

The remainder of this chapter reviews the supporting evidence for the genetic predisposition to various clinical groups of IBD and the progress in gene identification. This evidence includes ethnic differences in disease frequency, familial aggregation, an increased monozygotic (MZ) twin concordance rate compared with that in dizygotic (DZ) twins, the existence of genetic syndromes that feature IBD, loci for CD and UC identified by genome

scan and fine mapping, and finally, associations between various forms of IBD and specific genetic markers.

## 68.2 PHENOTYPIC HETEROGENEITY

Patients with UC or CD show great variability in their disease phenotypes for such characteristics as age of onset, rate of relapse, fibrostenosis, perforating/fistulizing, internal or perianal “penetrating disease” (fistulae, abscesses, or perforations), presence of diarrhea, bleeding or mucus discharge, duration of disease, location of disease (small bowel only, ileocolonic, colon only), number and types of surgery, development of chronic pouchitis after colectomy, and response to classes of medications such as corticosteroids, sulfasalazine or oral mesalamine, immunomodulatory agents (e.g. 6-mercapto-purine/azathioprine, methotrexate, cyclosporine), antibiotics, and topical therapies for distal colonic disease. Increasing evidence supports the clinical subgrouping of CD into perforating and nonperforating forms (12–14). Perforating CD is the more aggressive form, has a higher reoperation rate, and often results in abscesses and/or free perforation and fistulae. In contrast, the nonperforating form follows a more indolent clinical course and is associated with obstruction and bleeding (15). This clinical subgrouping has been further supported by cytokine mRNA profiles (16) and genetic marker studies (17–19). Some patients can be clearly classified as having CD based on histologic criteria yet have the UC-like features of left-sided colitis, more continuous and more shallow inflammation on endoscopy, and response to topical therapy (14).

These phenotypic differences may reflect underlying differences in immunologic processes. IL-1 beta and IL-1 receptor antagonist mRNAs are increased in resected intestinal tissue from patients with nonperforating CD (the more benign form of CD) when compared with perforating CD (16). CCR9-positive lymphocytes and CCR9 expressed in thymus distinguish small bowel from colonic CD (20). CD patients from families with multiple cases tend to have an early age at onset and more extensive disease as compared with those from families with no other cases (21). Within families with multiply affected cases of CD, common familial patterns have been observed in the disease aggressiveness, age of onset (22) and disease location (21,23). Such familial distribution of clinical features suggests that certain genetic or environmental factors shared by family members may determine the clinical course of the disease. Thus, it may be beneficial to study a clinically homogeneous group in order to understand the role of certain genetic or environmental factors.

Further observations support the concept that the serum expression of pANCA and ASCA reflect mucosal processes. For pANCA, B-cell clones taken from the mucosa of UC patients express pANCA (12), directly demonstrating pANCA in the intestinal mucosa. For ASCA, the specificity of the expression of antimannan

antibodies, rather than antigliadin or antiovalbumin in CD patients (24), of antibodies to *Saccharomyces* and not to *Candida* (25) and of the expression of ASCA in patients with CD, rather than with UC or other colitides, suggests that ASCA expression manifests a CD-related immune response rather than reflects a nonspecific intestinal insult resulting from the inflammation.

The expression of pANCA or ASCA has also been shown to extend the observed variability in IBD phenotype and provides further evidence for distinct subgroups within UC and CD. Within UC, the presence of pANCA has been associated with more severe forms of UC (treatment-resistant and left-sided UC (26), and the development of pouchitis following an ileal pouch-anal anastomosis (IPAA) procedure (27). Within CD, the presence of pANCA is associated with a more UC-like disease (more left-sided colitis, more distal, continuous, or shallow endoscopic appearance, more superficial histopathology) (14). Using pANCA as a phenotype, the authors have also provided evidence for heterogeneity within UC with family data (28) and this heterogeneity appears to have a genetic basis, as demonstrated by the use of HLA class II (29) and the intercellular adhesion molecule-1 molecular polymorphisms (see later, Candidate Genes) (30). High titers of ASCA in CD are associated with early age of disease onset as well as with both fibrostenosing and internal penetrating disease; in contrast, high ANCA levels are associated with a later age of onset and different disease location (13). These serum antibody observations are summarized along with other subclinical markers in Table 68-2.

Because increasing evidence points to the role of an aberrant innate immune response or T-cell response to enteric bacteria (see later), characterization of the serum expression of these antibodies may give clues to the specific microbial antigens involved in IBD pathogenesis. Western blots demonstrated that pANCA monoclonal antibody reacts to an unidentified *Bacteroides caccae* antigen and to an *Escherichia coli* outer membrane porin (OmpC) (54). Subtractive cloning, using tissue from CD patients taken from lesions and nearby uninvolved tissue, led to the identification of I2, a *Pseudomonas aeruginosa* sequence that acts as a potent superantigen for CD4<sup>+</sup> T-cell response (55,56). OmpC, I2, ASCA, and pANCA have all been shown to be expressed in the sera of CD patients with more severe disease, characterized by small bowel involvement, frequent disease progression, longer disease duration, and greater need for intestinal surgery, and expression of more than one antibody is associated with more severe disease (57,58). Serum expression screening has been used to identify specific bacterial antigens that drive IBD in the C3H/HeJBir mouse model of colitis. A lambda DNA expression library was first constructed from bacteria obtained from mouse ceca and then screened with sera from colitic mice. A large proportion of the positive clones from this study were sequences related to bacterial flagellin from *Butyrivibrio*,

**TABLE 68-2 Subclinical Markers for Inflammatory Bowel Disease**

Disease	Marker Studied	Type of Relatives	Observation	References
Combined IBD	Autoantibodies to epithelial-cell-associated component (ECAC) antigens	Family members	ECAC-C observed in 69.7% CD patients, 55.7% relatives, and only 8.0% control subjects	(31)
	Antinuclear autoantibodies (ANA)	Family members	ANA observed in 18% CD patients, 43% UC patients, 13% of relatives of CD patients, 24% of relatives of UC patients, 2% control subjects	(32)
	Goblet cell autoantibodies (GABs)	Family members	Positive GABs in 39% UC, 30% CD, 21% first-degree relatives of UC, 19% first-degree relatives of CD, 3% infectious enterocolitis, 2% healthy control subjects	(32)
	C-reactive protein (CRP)		High specificity to differentiate CD from other functional bowel disorders Higher levels associated with higher disease activity and need for colectomy	(33–35) (36)
Crohn's disease	C3 dysfunction	Family members	Greater C3 dysfunction in CD (38%) and relatives (18%) than in control subjects	(37)
	Intestinal permeability	Family members and twins	Increased in CD patients, conflicting results regarding relatives	(38–42)
	Obligate anaerobic fecal flora	Family members	The flora of CD patients contained more anaerobic gram-positive coccoid rods and more gram-negative rods than that of healthy subjects; during 5–7 years follow-up, three of nine children with CD with a CD floral pattern showed CD symptoms and one such child was diagnosed as CD. None of the 17 children with a normal flora showed CD symptoms	(43)
	Subclinical intestinal inflammation (fecal calprotectin)	Family members	Calprotectin in CD patients (47 mg/L) and relatives (11 mg/L) higher than controls (4 mg/L), but not spouses (4 mg/L)	(44)
	Anti- <i>Saccharomyces cerevisiae</i> antibodies (ASCA)	Family members and twins	ASCA increased in CD patients as compared with control subjects ASCA positive in 50% CD, increased in healthy relatives	(25,45,46). Also see text
	Pancreatic autoantibodies	Family members	Positive pancreatic autoantibodies in 27% CD (144% type I, 13% type II), subtype showed familial cluster, 0.5% in first-degree relatives	(47)
Ulcerative colitis	Antineutrophil cytoplasmic antibodies	Family members and twins	Specific for UC, increased in healthy relatives of UC patients, occur in a subset of CD patients	(48–51). Also see text
	Colonic mucins	Twins	HCM species IV (mucin subtype) reduced in both UC and healthy cotwins as compared with control subjects	(52)
	Mucosal production of IgG subclass	Twins	UC patients and their healthy MZ cotwins showed a raised proportion of IgG1 (78%) as compared with control subjects (56%)	(53)
	IgA against gliadin	Twins	High IgA titers against gliadin in both UC patients and their healthy cotwins	(24)

CD, Crohn's disease; HCM, human colonic mucin; IgA, immunoglobulin A; IgG, immunoglobulin G; MZ, monozygotic; UC, ulcerative colitis.

*Roseburia*, *Thermotoga*, and *Clostridium* species (27%). However, none of the sequences directly matched a flagellin already identified and in the GenBank database (59). The fact that bacterial flagellin is one of the ligands of the Toll-like receptor TLR5 supports the role of the innate immune system in the pathogenesis of IBD (see later) (60). The most reactive antigen, CBir1 flagellin, was also expressed in sera from human patients with CD independent of the expression of the others (59).

When taken together, these observations suggest that ASCA, pANCA, I2, OmpC, and CBir1 are serum markers for different mucosal inflammatory mechanisms that underlie distinct disease expression, and that genetic variation may underlie these mechanisms. Rather than a complete loss of tolerance to all microbial antigens, IBD is characterized by subsets of patients with different responses to specific microbial antigens (58,61). Use of clinical (fistulizing, perforating, fibrostenotic) and subclinical (ANCA,

ASCA) characteristics may be useful in subdividing patient populations into more etiologically homogeneous groups for genetic studies and thus be the means for unraveling the genetic heterogeneity of these diseases in the future. In addition to giving clues on the bacteria and the specific immune defects that lead to the pathogenesis of IBD, these antibodies hold future promise for diagnosis of subsets of IBD and thus for specific treatments.

### 68.3 RACIAL AND ETHNIC DIFFERENCES

Because the etiology of IBD is unknown, descriptive epidemiology plays a critical role in indicating the potential importance of genetic and environmental factors. However, owing to the difficulty of conducting population-based epidemiologic studies for these diseases, estimates of incidence and prevalence, especially in nonwhite populations, are imprecise. With the available data, the following can be generalized (62,63). Whites have a higher risk than nonwhite populations (64–66). There seems to be a north-to-south gradient in both North America and Europe (66–68), and IBD appears to be less common in developing countries. In North America and Europe, the most rapid increase of IBD occurred from 1960 to 1980 (63,66,69,70). For the white population in North America (Manitoba), the annual incidence rate of IBD (per 100,000) from 1989 to 1994 was 14.6 for CD and 14.3 for UC, and the prevalence (per 100,000) in 1994 was 198.5 for CD and 169.7 for UC (71). For a similar period (1983–1993), a somewhat lower incidence and prevalence was observed in Minnesota (incidence: 6.9 and 8.3 per 100,000 for CD and UC, respectively) (69,70,72). IBD risk in Europe is similar to that in North

America (67,73–77). A careful epidemiologic study of northern France has demonstrated that the incidence of CD has continued to increase in this region, rising from 5.2 per 100,000 from 1988 to 1990 to 6.4 per 100,000 from 1997 to 1999, and the incidence of UC has decreased from 4.2 to 3.5 per 100,000 in the same time periods (78).

In the United States, the white population has the highest risk among all ethnic groups, then blacks, followed by Mexican-Americans, and Asians (64,66,79,80). In the United States, blacks with CD have a higher incidence of associated arthritis and uveitis compared with whites, and Mexican-Americans with UC have a higher incidence of pANCA expression (100% for Mexican-Americans compared with 40% for blacks) (81).

Outside of North America and Europe, the incidence of CD has been increasing recently, for example, in Puerto Rico (from 0.49 to 2 per 100,000) (82), Taiwan (from 0.85 to 2.4 per 100,000) (83), and Hong Kong for both CD (from 0.3 to 1.0 per 100,000) (84). These increases suggest that an increase in Westernization may cause an increase in CD incidence (59).

Although the differences in IBD frequency among various ethnic groups can have both environmental and genetic explanations, important evidence for a genetic component to IBD susceptibility is the consistently increased incidence/prevalence in the Ashkenazi Jewish population compared with other ethnic groups in the same geographic location. The fact that the Jewish and non-Jewish differences occur across different time periods as well as different geographic areas (85–87) strongly suggests the existence of a genetic predisposition as the most parsimonious explanation (Table 68-3).

**TABLE 68-4 Positive Family History of Inflammatory Bowel Disease in Ulcerative Colitis (UC) and Crohn's Disease (CD) Probands<sup>a</sup>: An Example**

Disease in Probands	Number of Crohn's Probands <sup>b</sup>	Disease in Relatives			
		UC (%)	Disease (%)	Mixed <sup>c</sup> (%)	Total (%)
UC	269	37 (13.8)	6 (2.2)	4 (1.5)	47 (17.5)
Crohn's disease	258	19 (7.4)	32 (12.4)	9 (3.5)	60 (23.3)
Total	527	56 (10.6)	38 (7.2)	13 (2.5)	107 (20.3)

<sup>a</sup>See Reference (105).<sup>b</sup>Both Jews and non-Jews have the same trend.<sup>c</sup>With several affected relatives, some affected with UC and some with CD.

Further support for this hypothesis comes from studies of the historical origins of Jewish subgroups and their relation to IBD frequency (86,97–99).

## 68.4 FAMILIAL AGGREGATION

More than a dozen studies have demonstrated that familial aggregation is clearly increased in IBD although the data fit no simple Mendelian pattern of inheritance (30,76,87). Several studies have shown that there is an approximate 10- to 30-fold increase in disease prevalence among siblings compared with the communitywide prevalence (100–104). In addition to an increase in UC in relatives of UC patients and in CD among the relatives of CD patients, both UC and CD may exist in the same families, with an increased frequency higher than the co-occurrence by chance alone, suggesting an etiological relationship between UC and CD (Table 68-4) (105,106). These families may identify a specific subset of IBD (mixed IBD), which currently would be defined by family history (105). Positive family history is somewhat greater among CD patients than among UC patients (105–107), and the relatives of CD patients have a higher risk for IBD than those of UC patients (105,108). This suggests that CD is, to some degree, more often familial than UC and that CD has a greater genetic component (as will be seen later, this is supported by the twin data). The authors' family data represent the observations regarding familiarity well (Table 68-4; 105). In that study, the age of relatives was also taken into account to estimate the lifetime risks for disease. The lifetime risks for the relatives of non-Jewish patients were consistently lower than the corresponding risks for relatives of Jewish patients from the same geographic area (Table 68-5). This has implications for the mode of inheritance of genetic susceptibility (see later).

The serum expressions of ANCA and ASCA have also been observed to be familial traits. An increased frequency of ANCA expression has been observed in the clinically healthy relatives of UC patients compared with environmental controls (49,28). Second-degree relatives, who did not share the same household with the probands, had an increased prevalence of ANCAs, and

**TABLE 68-5 Empiric Risks for Inflammatory Bowel Disease (IBD) in First-Degree Relatives of Patients with Inflammatory Bowel Disease<sup>a</sup> (%)**

	Sibling	Parents	Offspring	Total
<b>Uncorrected empiric risks for relatives of IBD probands</b>				
<i>Jewish probands affected with</i>				
Crohn's disease	8.0	3.0	1.8	4.5
Ulcerative colitis	2.4	3.2	1.9	2.6
<i>Non-Jewish probands affected with</i>				
Crohn's disease	3.0	3.7	0	2.7
Ulcerative colitis	0.4	0.9	2.3	0.9
<b>Corrected empiric lifetime risks for relatives of IBD probands<sup>b</sup></b>				
<i>Jewish probands affected with</i>				
Crohn's disease	16.8	3.8	7.4	7.8
Ulcerative colitis	4.6	4.1	7.4	4.5
<i>Non-Jewish probands affected with</i>				
Crohn's disease	7.0	4.8	0	5.2
Ulcerative colitis	0.9	1.2	11.0	1.6

<sup>a</sup>See Reference (105).<sup>b</sup>Corrected for age of at-risk relatives, using age-specific incidence data.

the household controls were not at an increased risk for ANCA. These observations suggest that the familial aggregation of ANCAs is due to shared genetic factors among the family members, and not shared environmental factors. Furthermore, in these family studies, there was a significant difference in the frequency of ANCAs in the relatives of probands whose sera were ANCA(+) compared with the relatives of probands whose sera were ANCA(–). This concordant familial distribution indicates heterogeneity within UC. Thus, ANCAs may be used as a marker of an underlying immunologic disturbance that is genetically determined (50).

The authors have demonstrated that the level of serum ASCA expression is a quantitative trait that is also familial in both affected and unaffected relatives of CD patients using intraclass correlation analysis (109). A high percentage of CD patients (approximately half) and affected family members (also approximately half but with a lower level of expression) were seropositive for antimannan antibodies, compared with the normal control population (3.7%). Seropositivity or seronegativity was correlated

among all affected relatives and this association was stronger in affected first-degree relatives. Intraclass correlation revealed less variation in ASCA levels within, rather than between families, and a significant familial aggregation was observed. There was no significant correlation among marital pairs. These findings demonstrated that ASCA in family members affected and unaffected with CD is a familial trait for both affected and unaffected relatives. The lack of correlation in marital pairs suggested that this familial aggregation is due in part to a genetic factor or childhood environmental exposure.

## 68.5 TWIN AND SPOUSE STUDIES

Although it is possible for the familial aggregation described in the preceding section to be due to environmental factors alone, additional support for a major genetic component to IBD susceptibility is provided by increased MZ twin concordance rates, the rarity of IBD concordance in spouses, and the numerous instances of affected relatives completely separated geographically and temporally from other affected family members.

Even though twin data must be interpreted with caution, because concordant pairs are more likely to be reported than discordant pairs, several studies have shown an increased concordance rate of both CD and UC in MZ twins when compared with DZ twins (110,111). In order to circumvent this selection bias, population-based twin studies have also been conducted with the same higher concordance rate for MZ twins than that for DZ twins for both CD and UC (112–114). The concordance rate for CD is also higher than for UC (for example, the Swedish population-based study observed an MZ twin concordance of 58% for CD and 18% for UC). The higher concordance rate in MZ twins than in DZ twins supports the hypotheses that genetic factors are an important component in the development of IBD and that genetic factors account for much of the familial aggregation. The observation that <100% of MZ twins are concordant indicates that there is reduced penetrance for the IBD genotype, presumably due to nongenetic factors. These nongenetic factors may be environmental or they may be due to the random stochastic variation, for example, in the development of the B cells and T cells of the immune system (115,116). The observation that the risk to DZ twins is not higher than the risk to siblings argues that the environmental factors are population-wide in their effect.

From the limited number of family studies investigating the risk in spouses, it seems that the incidence of reported spouse concordance does not appear to be increased over population risks, and is dramatically less than the risk to siblings (30,102,111). This observation argues against any rapid-acting environmental agents; there are, however, case reports of husband–wife couples that both developed IBD after marriage (see also below, Multilocus Model, and Gene and Environmental Interactions) (117).

Therefore, these genetic epidemiologic studies of differences in IBD in various populations, of familial aggregation, and of twins and spouses of the affected have contributed to the basic concept that there is a major genetic contribution to susceptibility to IBD or diseases.

## 68.6 INFERENCES REGARDING MODE OF INHERITANCE

Although there is a strong familial aggregation of IBD and a major genetic component contributes to such familiarity, there is no one simple genetic model that can explain the mode of inheritance of this disorder. The following observations must be considered when exploring potential genetic models (118). From the MZ twin data, these are diseases with reduced penetrance, that is, genetic susceptibility does not appear to be the only determinant of disease (119). The fact that DZ twins have a risk similar to that of siblings suggest that it is macro- (over a wide area), not micro- (within an individual household) environmental factors that determine the risk to IBD (120). CD and UC are clearly genetically related, because they are (a) found together with increased frequency in families, (b) both increased in the Jewish population compared with the surrounding white population, and (c) distributed in the same countries of origin for US. Ashkenazi Jewish patients with IBD (62,121). On the basis of the stronger family history of IBD and greater MZ twin concordance for CD, genetic determinants appear to play a more deterministic role in CD than in UC. This does not mean that UC is any less genetic but may be more influenced by stochastic variation (122). There is now evidence for the involvement of specific loci and genes (Section 68.10) (123). Genetically modified animal models suggest that different genes can cause the same clinical phenotype (124). Animal models also indicate the importance of gene and environmental interactions (125). These observations and their implications for the mode of inheritance are summarized in Table 68-6.

### 68.6.1 Simple Mendelian Model

Segregation analysis of the aggregation of disease within families demonstrates that IBD is not inherited in any simple Mendelian mode of inheritance (105,126). Using a computerized genetic analytic technique termed *complex segregation analysis*, a recessive gene with incomplete penetrance was proposed for CD (127,128), and an additive major gene or a dominant major gene was proposed for UC (128,129). However, the conclusion of a major gene effect from complex segregation analysis is not equivalent to the conclusion of a major gene with simple Mendelian inheritance. Although these analyses argue strongly against the multifactorial/polygenic model (discussed later), they cannot distinguish

between simple Mendelian models and models with several major genes interacting (also known as multilocus or oligogenic model, see later), or models of genetic heterogeneity (i.e. several genetically distinct diseases with a similar phenotype). Nevertheless, keeping the genetic heterogeneity of IBD in mind (see later), the possibility of simple Mendelian susceptibility may be true for a subset of IBD. If so, even though these forms are rarer, the collection of families showing Mendelian segregation and subsequent locus and then gene identification within these families may be fruitful in showing biochemical or immunologic pathways relevant to the non-Mendelian and more frequent forms of IBD. This line of inquiry proved very fruitful for uncovering the roles of the low-density lipoprotein (LDL) receptor in cholesterol metabolism (130) and of ion transporters in hypertension (131).

**TABLE 68-6 Genetic Inferences Based on Evidence of Family Aggregation in Inflammatory Bowel Disease (IBD)**

1.	IBD exhibits familial aggregation	Increased risk factors within families
2.	(a) Monozygotic twin concordance > dizygotic twin concordance (b) No increase in spouses	Genetic factors responsible for familial aggregation
3.	(a) Positive family history in CD > UC  (b) Twin concordance of CD > UC	CD is more genetic or more deterministic; UC may be more stochastic and thus more immunologic
4.	Both CD and UC occur in the same families	Some genetic aspects of CD and UC are shared
5.	Very few "mixed" MZ twin pairs	Some genetic aspects of CD and UC are distinct
6.	Risks are much greater in families than in the population	Genetic susceptibility is not polygenic
7.	Familial risks in Jews > familial risks in non-Jews in neighboring area	Genetic susceptibility is not simple Mendelian
8.	Non-Jewish families have proportionally more "mixed" IBD (CD and UC) than Jewish families	"Mixed IBD" is not a simple overlap, but possibly a different disease, thus evidence for genetic heterogeneity
9.	Clinical features concordant in CD families	Genetic heterogeneity
10.	Increased risks to offspring when both parents have IBD	Limited number of disease genes
11.	Dizygotic twin concordance = sibling risk	Environmental factors are probably not micro-environmental but macroenvironmental

CD, Crohn's disease; MZ, monozygotic; UC, ulcerative colitis.

## 68.6.2 Multifactorial/Polygenic Model

In order to explain familial aggregation that does not follow a Mendelian pattern of inheritance, the polygenic model proposes that many genes, each with a small contribution to the phenotype, together provide the susceptibility to disease when the individual crosses a certain threshold. This model is termed multifactorial when these many genes must also interact with environmental factors. A polygenic model has been proposed to explain the association between CD and UC and to explain why the relatives of people with CD are much more likely to have IBD than the relatives of people with UC. The features of this model are the following: (1) a single genotype, comprising 10 or 15 genes, makes individuals susceptible to IBD (107); (2) if a person has only a few of these genes, they are more susceptible to UC, whereas if they have most of these genes (a more complete genotype), they are more susceptible to CD. Relatives of those patients with most of the genes (CD patients) would also be more likely to have a larger number of IBD susceptibility genes than the relatives of patients with only a moderate number of the risk genes (UC patients). Thus, CD patients would be more likely to have relatives with UC, whereas UC patients would be more likely to have relatives with too few of the high-risk genes to have any form of IBD.

However, the formal mathematical genetic analyses of large family data sets of both UC (128,129) and CD (127,128) have allowed the rejection of the polygenic model. Basically, the risk of relatives is too great to be explained by this model. In addition, genetically modified animal models (including knockouts) suggest that if one gene in the immunoregulatory pathway is sufficiently altered, it can lead to clinical disease; thus, multiple genes with equal but small effects may not be required.

## 68.6.3 Multilocus (Oligogenic) Model

There is increasing evidence that the genetic predisposition to a number of diseases is due to the interaction of two or more major genes, a form of inheritance termed two locus (if two major genes are involved), or multilocus or oligogenic (if more than two are involved) (132–138). This model is important for IBD for several reasons. First, it is etiologically attractive because it is able to explain the occurrence of more than one pathophysiologic defect in IBD patients. For example, in order to develop clinical CD, one may need both a permeability defect that leads to increased exposure of the body's immune system to antigenic substances that ordinarily do not cross the gut mucosal barrier and a particular genetically determined immune response. An analogous hypothesis might include abnormal mucins and certain autoantibodies as the etiologic factors in UC. Second, the multilocus model is able to explain the disparity between IBD recurrence risk estimates and typical

risk estimates for Mendelian disorders (134–136,138). Third, the multilocus model is able to explain the relationship of UC and CD in families. For example, one gene may be insufficient by itself to lead to clinical disease yet predisposes to both diseases, but clinical disease occurs only when a second more specific gene interacts with the first and leads to the specific disease, either UC or CD. Fourth and finally, the multilocus model makes genetic counseling and risk identification in relatives feasible once the first susceptibility locus is identified, as has been demonstrated for other autoimmune diseases (Section 68.10) (136).

In one intriguing study, the risk of IBD in offspring when both parents have IBD is (1) more than twice the empiric risk to offspring of couples when one parent has IBD, (2) similar to the empiric risk for identical twins, and (3) is higher for CD than for UC (139). The risk to offspring was similar whether both parents, one parent, or neither parent had developed symptoms of IBD at the time of the conception. Furthermore, the concordance rates for the type of IBD (UC or CD) in these couples were similar whether both experienced the onset of IBD before marriage, one before and one after, or both after marriage. These observations suggest that genetic and not acquired factors are essential in the development of IBD and in the determination of the type of IBD, whether UC or CD. Furthermore, although strong environmental determinants limited to certain families could be an explanation, these data support the concepts of a limited number of genetically determined forms of IBD, of a limited number of IBD-predisposing genes, and of the multilocus/oligogenic model for IBD susceptibility. If many different genes were required or if there were many different genetic forms of IBD, then genetic complementation would reduce the risk to offspring. However, if there are a limited number of such genes, then the offspring of two affected parents are more likely to be homozygous at the loci for such genes and consequently affected.

The number of genomic regions thus far identified using genome screen methods and the identification of several candidate genes further support the multilocus/oligogenic model (see later).

#### 68.6.4 Genetic Heterogeneity Model

The heterogeneity model proposes that IBD is not a single disease but rather several diseases with different etiologies but presenting the same clinical picture. Advantages of this model are that, first, the identification of clinical subgroups leads to understanding separate etiologies corresponding to each of the specific subtypes of IBD and, thus, unravels an otherwise bewildering array of phenotype/genotype relationships, and second, genetic heterogeneity leads to testable etiologic hypotheses. The following observations support the idea of the genetic heterogeneity of IBD. (1) IBD is phenotypically

heterogeneous with emerging evidence on clinical subtypes (see earlier). (2) IBD is a feature of several different genetic syndromes (see later). (3) Animal models engineered by targeted gene disruption (knockout mice) illustrate that there are many pathophysiologic pathways to the development of IBD (140–142,125); (4) The different relative frequencies of mixed disease (CD and UC) in the same family in Jewish versus non-Jewish families argue that the mixed form may be a distinct subgroup (105).

Genetic heterogeneity leads to the predictions that genetically determined physiologic abnormalities in the affected case are likely to be shared with their relatives and that these would be similar within the same clinical subgroup. In this way, further support for the genetic heterogeneity of IBD comes from (5) the genetic serum expression of pANCA or of ASCA define clinical subtypes of disease and are also present in the unaffected members of the family of affected (see later), and (6) the association of specific genetic markers with clinical subtypes within CD and UC associations also suggest heterogeneity within CD and within UC (see later).

Therefore, the available evidence support the concepts that IBD is a genetically heterogeneous group of disorders, with each subform an oligogenic disorder due primarily to the interaction of a limited number of genes, although there may be more minor contributions from modifying genes.

### 68.7 ASSOCIATION OF IBD WITH RARE GENETIC SYNDROMES

IBD is clearly associated with three well-defined genetic syndromes: Turner's syndrome (143), Hermansky–Pudlak syndrome (HPS) (OMIM #203300) (144–147), and glycogen storage disease type 1b (GSD1b) (OMIM #232220, Chr 11q23) (148,149). In addition, IBD has been less clearly associated with several immunodeficiency syndromes (Table 68-7).

**TABLE 68-7 Genetic Syndromes Associated with Inflammatory Bowel Disease**

Turner's syndrome
Hermansky–Pudlak syndrome
Glycogen storage disease type 1b
Sickle cell disease
Trisomy 9
Immunodeficiency disorders
Secretory immunoglobulin deficiency
Agammaglobulinemia/hypogammaglobulinemia
Selective IgA deficiency
Chediak–Higashi syndrome
Complement 2 (C2) deficiency
Hereditary angioedema
Pachydermoperiostosis

IgA, immunoglobulin A.

### 68.7.1 Turner's Syndrome

Several reports of patients with Turner's syndrome (Chapter 44), that is, individuals who lack all or part of one X chromosome, leave little doubt that the incidence of IBD is many times higher than that seen in the general population (85,150,151). This association may be due to the abnormal state of a single X chromosome; IBD has also been linked to the X chromosome in genome scans (152,153). Alternatively, patients with Turner's syndrome are known to be at increased risk of several diseases thought to involve autoimmunity (150). It may not be too surprising that IBD, also a potential autoimmune disease, is increased in these patients. CD and UC have been reported in about equal numbers in patients with Turner's syndrome.

### 68.7.2 Hermansky–Pudlak Syndrome

HPS (Chapter 145) is a tyrosinase-positive form of oculocutaneous albinism with a lysosomal storage defect leading to accumulation of ceroid lipofuscin and with a platelet aggregation defect leading to a bleeding diathesis (147). The pattern of inheritance is autosomal recessive; many genes have now been identified, showing genetic heterogeneity in this disorder and multiple mutations have been observed with different subphenotypes, showing locus heterogeneity (154,155). HPS1 is rare except in the Puerto Rican population (where it is the most common genetic disorder with an incidence of 1:1800) and an isolated village in the Swiss Alps. The *HPS1* gene (OMIM \*203300, Chr 10q23.1) was identified by linkage and positional cloning of families from these populations and is the homolog of the mouse "pale ear" gene (156–158). Different mutations at the HPS1 locus have been shown to be associated with IBD (159).

HPS2 (OMIM #608233, Chr 5q14.1) differs from the other forms of HPS in that patients are immune deficient and susceptible to infections. HPS2 mutations are located in the beta-3A subunit of the adaptor protein complex 3 (AP3); AP3 forms transport vesicles for sorting protein traffic to lysosomes, melanosomes, and platelet granules (AP3B1, OMIM \*603401) (160). The identification of the altered protein in HPS2 is, therefore, consistent with the pathophysiology of HPS and focuses further investigation on protein trafficking pathways for this disorder. Alterations in protein trafficking have also been observed to affect NK T-cell development (161) and antigen presentation because endocytosed microbes are delivered to lysosomes for binding to MHC and CD1 molecules (162).

Proteins HPS1 and HPS4 (OMIM \*606682, Chr 22q11.2-12.2) (163) form a complex that is involved in the biogenesis of lysosome-related organelles (BLOC-3, biogenesis of lysosome-related organelles complex 3) (164,165). The role of HPS2 in cellular trafficking suggests that BLOC-3 is involved in a perhaps earlier step

in sorting of proteins to organelles (166). HPS3 (OMIM \*606118, Chr 3q24; syntenic with murine *coa*), HPS5 (OMIM \*607521, Chr 11p15-p13), and HPS6 (OMIM \*607522, Chr 10q24.32) form complex BLOC-2 (167,168) and HPS3 is involved in the early stages of melanosome biogenesis and maturation (169,170).

Interstitial pulmonary fibrosis with pulmonary insufficiency has been reported as the most frequent and serious complication of HPS1 (147,166,171). In addition, a form of granulomatous colitis was reported in 5/9 HPS1 albinos in two Puerto Rican families living in New York and in 12/37 patients living in Puerto Rico (65,147). HPS and granulomatous colitis are rare in non-Puerto Ricans (144). The clinical diagnosis in these colitis patients was UC, but the resected colons showed long linear ulcerations and microscopically focal mucosal non-necrotizing granulomas similar to CD but with variable amounts of brown granular pigment (65). In general, colitis has been refractory to medical treatment and appears to require surgical resection (147). No defect in peripheral blood lymphocyte or neutrophil function was identified (146).

### 68.7.3 Glycogen Storage Disease Type Ib

GSDIb (OMIM #232220) is an inherited metabolic disorder caused by a defect in the glucose-6-phosphate transporter (G6PT1; OMIM #602671). GSDIb contrasts with GSDIa (OMIM +232200), caused by a deficiency in the glucose-6-phosphatase (G6Pase) activity (Chapter 93). GSDIb is distinguished clinically from classic GSDIa by a predisposition to recurrent infections due to neutropenia and neutrophil dysfunction (123,172,173). In a study of 36 GSDIb patients from North America, 75% of subjects had some gastrointestinal symptoms and 28% had documented CD, and an additional 22% had symptoms highly suggestive of CD but had not been diagnosed (174). CD is, therefore, associated with GSDIb, implicating neutrophil abnormalities in the pathogenesis of IBD (148,175–177). Neutrophils in GSDIa also show increased apoptosis (178). Long-term treatment with colony-stimulating factors (CSF2, OMIM \*1389600, alias granulocyte–macrophage colony-stimulating factor, GM-CSF, and CSF3, OMIM \*138970, alias granulocyte colony-stimulating factor, G-CSF) normalizes neutrophil count (179). Treatment with CSFs heals oral and intestinal mucosal lesions from CD in GSDIb (149,180). CSF3 is also in trial for treatment of non-GSDIb CD as an alternative to immunosuppression (181–183).

### 68.7.4 Immunodeficiency Syndromes

The role of neutrophils in CD pathogenesis is further supported by the observations of CD-like lesions in neutrophil or bone marrow stem cell disorders: chronic granulomatous disease (124,184,185), congenital neutropenia (186), autoimmune neutropenia (187), leukocyte adhesion deficiency (188), and

myelodysplastic syndromes (Table 68-7) (189–191,588). A very interesting observation is that gut inflammation disappeared after stem cell transplantation for myeloid leukemia and myelodysplastic syndrome; this alleviation of inflammation persisted after immunosuppression was discontinued (192).

## 68.8 ASSOCIATIONS WITH OTHER DISEASES

The association of IBD with many immune-related disorders with unknown etiology is well documented; these disorders include ankylosing spondylitis (AS), psoriasis, primary sclerosing cholangitis (PSC), and pouchitis. IBD may also be associated with autoimmune disease in general.

### 68.8.1 Ankylosing Spondylitis

In UC patients, the frequency of AS (OMIM #106300) ranges from 1% to 6%, and of arthritis from 2% to 15% (193). In CD patients, the frequency of all arthropathies ranges from 5% to 10% (193–195). The frequency of the MHC allele HLA-B27 is greatly increased in AS patients (90% compared with a frequency of 10% in the general population) (196–202). In the HLA-B27 transgenic rat model of IBD, gut bacteria have been associated with both gut inflammation and arthropathy (203). Thus, an increase in IBD risk is associated with factors that also increase the risk for AS, particularly HLA-B27, suggesting that IBD is a potent initiating or attenuating factor in the development of AS (204). It is still not certain whether AS should be considered a complication of IBD or an associated disease. Bowel permeability is altered in AS patients and their relatives (205), and bowel disease may be present with AS even when it is not manifested clinically (206–208). Patients with non-AS spondyloarthropathy and inflammatory gut lesions have a greater risk of developing AS than patients without gut inflammation (209–211). Furthermore, relatives of IBD patients have an increased risk for AS even when the IBD patients themselves have no evidence of AS (212).

### 68.8.2 Psoriasis

Psoriasis (OMIM #177900) is a chronic inflammatory dermatosis that affects 2% of the population in North America. Psoriasis is increased in CD patients (7–11% compared with 1.1–1.6% in the general population), as well as in the relatives of CD patients (213–215). The concurrence of psoriasis and CD at both the individual level and family level suggests the possibility of a genetic link between the two disorders. Genomewide scans for psoriasis have identified many susceptibility loci; 6p21.3 (HLA or major histocompatibility region, MHC) and 17q25 are well established, and there is some linkage

evidence for loci at 1p, 3q21, 4q31–q34, 17q, and 19p13 (216–222). These data are consistent with the hypothesis that some genetic determinants are common for both disorders (see later).

### 68.8.3 Primary Sclerosing Cholangitis

PSC (OMIM #260480) is familial (223), and the association between PSC and UC has been recognized for several decades (224–227). The prevalence of PSC among UC patients is approximately 5% overall and 10–15% among UC patients with hepatic abnormalities (225,228,229). The association is stronger in reverse, with approximately 50–70% of all PSC cases affected with UC. This may be an underestimate, because IBD onset may have a substantial subclinical phase of IBD far longer than previously appreciated (230). There is no difference in PSC-related survival among patients with or without IBD (231). Cigarette smoking and appendectomy increase the risk for all extraintestinal manifestations in UC, including PSC (232). The following studies have demonstrated similarities in the immune response between these two disorders. First, a higher proportion of patients with PSC and UC have antibodies to colon antigens and to portal tract antigens of the liver (47,224). Second, a colonic epithelial protein has been identified with unique epitopes that are shared by the skin and biliary tract epithelial cells (233). Third, both UC and PSC express ANCA (49,234–237). If there is a common antigenic target for immune-mediated attack on both colonic and biliary epithelial cells, identification of this antigen may facilitate the understanding of the basic immunoregulatory disorder underlying both diseases and may foster development of an improved assay for a marker of both diseases. And fourth, both PSC and UC share HLA class II genetic risk factors. PSC risk factors include HLA-DR2 serotype and the HLA haplotype A1-B8-DR3 (238–241), and UC risk factors include HLA-DR2 (see later) and HLA-DR3 in a population in which HLA DRB1\*1502 (serologically DR2) is rare (242).

### 68.8.4 Pouchitis

Restorative proctocolectomy with ileal reservoir is a widely accepted procedure in the surgical treatment of UC (243). However, the most frequent long-term complication after IPAA for UC is a nonspecific inflammation of the ileal reservoir known as *pouchitis* (244). This complication seems to be disease related and not operation related, because the occurrence of pouchitis in patients after IPAA for familial adenomatous polyposis is significantly lower than that in patients after IPAA for UC (245). The cumulative risk of developing pouchitis varies between 15% and 46%, depending on the duration of follow-up (246). The etiology and pathophysiology of pouchitis are not well understood, but many of the risk factors are similar to those for UC. Pouchitis has

also been associated with the presence of extraintestinal manifestations of the UC, including PSC (247,248), of pANCA (27,249), and of the protective effect of smoking (250). Therefore, it appears that pouchitis reflects the same underlying etiology and pathophysiology of UC, indicating the importance of host factors, such as genetic susceptibility and immunologic functions.

### 68.8.5 Multiple Sclerosis

The concurrence of multiple sclerosis (MS; OMIM #126200) with IBD has been observed both within families (251,252) and within individuals (253–256). Of interest, a study of intestinal permeability in MS patients found that a fourth of patients with MS also had increased intestinal permeability (257).

One explanation for the association of IBD with other diseases is that the genetic component is a generalized defect of the immune system, which then may predispose the patient to several different autoimmune diseases or conditions. This hypothesis is supported by (1) the increased frequency of classic organ-specific autoimmune disorders observed in a large series of UC patients (e.g. autoimmune thyroid disease, insulin-dependent diabetes, and systemic lupus erythematosus) but not in CD patients (258–261); (2) the concurrence of UC and celiac disease (262,263); and (3) genome scans for several autoimmune disorders has shown that susceptibility to many autoimmune diseases share genomic regions, suggesting common susceptibility genes (264).

The hypothesis further suggests that the etiology of the complications of IBD affecting only a portion of IBD patients may also share this generalized autoimmune disorder. This would be an example of genetic pleiotropy, one gene altering many phenotypes. These complications of IBD include uveitis, erythema nodosum, pyoderma gangrenosum, hepatitis, pancreatitis, and cirrhosis (107). In a large family with members affected with different autoimmune disorders, including rheumatoid arthritis, systemic lupus erythematosus, psoriasis, and IBD, it appears that family members with the same disease tend to share the same major histocompatibility complex (MHC) HLA haplotypes (265). Variation of the MHC class I polypeptide-related sequence A gene (*MICA*; GeneID 4276), also located within the MHC, has been associated with UC and with peripheral arthropathy (266). These observations suggest that one set of genes may determine the general autoimmunity of a patient, whereas other genes govern the specific constellation of phenotypes.

## 68.9 GENE AND ENVIRONMENTAL INTERACTIONS

The family and twin studies discussed earlier and the genetic linkage and association studies reviewed later are evidence that genetic factors play an essential role

in the development of IBD. However, the following observations argue for an additional environmental contribution to human IBD: (1) disease incidence has exhibited temporal trends and is correlated with industrialization or “Westernization”; (2) there is much less than a 100% concordance rate in MZ twins; (3) different disease risks have been observed for the same ethnic group residing in different geographic locations; and (4) mouse models of IBD have demonstrated that intestinal bacteria are necessary for disease development. Therefore, it is likely that both gene and environmental factors determine the risk of developing IBD, and IBD is, thus, a complex genetic trait.

Although the relationship of environment to IBD is complex, epidemiologic studies have identified several environmental factors that increase susceptibility to IBD.

### 68.9.1 Smoking

Smoking appears to have a protective effect for UC (267), with UC patients less likely to be smokers (OR=0.17) (52,241,268–271). Smoking may reduce overall symptoms (272,273), the need for surgery (274), and pouchitis (250). In contrast, smoking is associated with CD (275). A large meta-analysis across seven studies showed that smoking is associated with a greater susceptibility to CD (pooled odds ratio [OR]=2.0, 95% confidence interval [CI] 1.65–2.47, for current smokers; OR=1.8, 95% CI 1.3–2.5 for previous smokers) (269). CD smokers showed a higher recurrence of repeat surgery through a 10-year follow-up period, particularly for women (OR=4.2 for women; OR=1.5 in men) (276), and this risk of recurrence is reduced when CD patients stop smoking (277). Interestingly, one study demonstrated that CD patients do not know about the effect of smoking on their disease (278). Smoking may interact with the IBD4 locus (see linkage results later) (279). Randomized placebo-controlled trials of transdermal nicotine in UC patients have demonstrated some clinical improvement but not disease remission (246,280).

### 68.9.2 Westernization

As noted above, IBD appears to rise as a country becomes “Westernized” or industrialized (63). For example, a negative correlation between infant mortality or household hygiene and the incidence of CD has been demonstrated (73,281,282). Many crucial changes occur in food, housing, transport, leisure, and clothing during this process, so that identification of the important exposure may be impossible. One recent hypothesis is that cooling of food during distribution and home refrigerators accounts for the rise in CD and is based on the following observations: (1) increases in incidence parallel public acquisition of refrigerators in the United States, Sweden, United Kingdom, and Southern Europe; (2) pathogenic psychotropic bacteria exist that are capable of growth within

refrigerators, particularly *Yersinia enterocolitica*; (3) CD lesions occur in regions of high lymphoid follicles, suggesting the role of specific infection; (4) CARD15 mutations (see later) affect phagocytic cell lines, including monocytes, targets of *Yersinia* infection (283).

### 68.9.3 Appendectomy

A meta-analysis of 17 case control studies describing 3600 cases and 4600 controls showed that appendectomy was associated with a 69% reduction in subsequent risk of developing UC (284). A large Australian study observed that appendectomy was associated with more extensive UC but with a reduction in the requirement for immunosuppression or colectomy for the treatment of colitis (285).

### 68.9.4 Intestinal Bacteria

The study of animal models of IBD has given clear evidence that gut bacteria are necessary for intestinal inflammation and that inflammation results from an aberrant activation of the immune system driven by the gut lumen bacteria (141,142,279,286,287). Inflammation develops when these various animals are raised in normal and in pathogen-free (SPF) conditions and does not develop when the animals are raised in very strict germ-free (GF) conditions (288). For example, inflammation does not develop with the IL10 knockout (ko) and TCRalpha ko mouse models grown in GF conditions (289,290); recolonization with *Bacteroides vulgatus* induces inflammation in both models and *Helicobacter hepaticus* alone induces inflammation in the IL10-/- (IL10 knockout) model (these bacteria are murine pathogens) (291,292). An *H. hepaticus* flagellar hook protein has been identified as one of the specific antigens that induces colitis in the IL10-/- model (293). *H. hepaticus* alone induces inflammation in many other animal models and is thus under active investigation by many groups (294,295). These knockout models also demonstrate that variation in many different genes leads to intestinal inflammation and show the greatest promise for investigating the relationships between cytokine genes and intestinal bacteria as well as the steps that lead to an imbalance between TH1 and TH2 cells in the intestinal immune system (141,287). Another mouse model is adoptive transfer: mice homozygous for the SCID mutation develop IBD when isolated CD4<sup>+</sup> T cells from another donor strain expressing high levels of CD45RB<sup>high</sup> antigen on their surface are transferred. Intestinal bacteria in the recipient mouse are also required for intestinal inflammation. This adoptive transfer model has demonstrated that both intestinal inflammation promoting and inhibiting cells are present in the intestinal immune system, and shows the greatest promise in dissecting the events in T-cell differentiation that lead to inflammation, particularly the relationship between the intestinal immune system

and the thymus (296). In one rat transgenic model, the human HLA-B27 and beta-2 microglobulin genes have been introduced to replace the rat ortholog. Animals develop multiorgan disease that resembles the human spondyloarthropathies that accompany IBD in some individuals, colitis, arthritis, orchitis, and psoriasiform changes of the skin and nails (297,298); both colitis and arthritis do not occur when B27 transgenic rats are raised under GF conditions, implicating the normal enteric bacterial flora as the source of the antigens driving these diseases (299). *E. coli* and *Enterococcus* spp. are correlated with the amount of inflammation (300). This model has clearly demonstrated the role of the MHC class I antigen presentation system and shows the greatest promise to elucidate how presentation induces both intestinal and extraintestinal inflammation. New and unexpected ways to treat IBD should emerge from the intensive study of all of these types of models (287).

The studies examined thus far clearly indicate the role of both genetic and environmental factors in the etiology of IBD. Clearly identifying the specifics of these risk factors will depend on the relative distribution of the particular factor. For example, in western societies, a common environment may have brought the majority of people to an equal footing in terms of good hygiene, better nutrition, and improved maternal and pediatric care. In this case, when the environmental factors are common to all within the society, those individuals with the IBD susceptibility genes will be more likely to develop the disease as compared with those who do not have such genes. In this case, identifying the IBD susceptibility genes is possible, whereas identifying the IBD susceptibility environmental factors will be difficult. In contrast, the situation in which the environmental factors are not so common, as in developing countries that are experiencing a rising incidence of IBD, offers a window of opportunity for finding the specific environmental factors that contribute to IBD. Finding the environmental factors will be easier as the IBD susceptibility genes are identified. Therefore, well-designed genetic epidemiologic studies in developing countries are warranted as the incidence of IBD increases; these studies will have benefit for North America in addition to that particular developing country.

### 68.9.5 An Evolutionary Perspective

One question that should be raised in the context of this broad discussion of the genetic and the environmental risk factors for IBD is, "Why are IBD susceptibility alleles so frequent in the population?" There are three theoretical possibilities.

First, IBD susceptibility could be due to new mutations. However, IBD susceptibility alleles clearly cause clinical disease with major morbidity and even mortality. The mortality was certainly greater until modern supportive management became available. If new mutations were the explanation, the mutation rate would have to

equal both the mortality rate and the decreased reproduction due to the disease. For new mutations to explain the IBD disease frequency in the modern world, the mutation rate clearly would have to be much greater than the estimated range of 1 in 100,000 to 1 in 1 million/gene locus that appears to be the mutation rate in humans.

Second, IBD susceptibility alleles could be the result of the founder effect. The founder effect refers to the concept that a given gene appeared (presumably by mutation) in a small ancestral population (i.e. in a founder) and by random chance was transmitted to a large number of that founder's offspring. This would establish the gene in relatively high frequency in the original small population and its subsequent ancestors (301,302). Although this founder effect is a reasonable explanation for the high frequency of certain genes in certain ethnic groups, it is an inadequate explanation for a disease (or diseases) with as wide a distribution and as high a frequency as IBD.

Third, IBD susceptibility alleles may convey a selective advantage, either now or under conditions in the past; IBD susceptibility alleles are frequent, even though deleterious (disease causing), because they also provide some compensating advantage to those individuals who have them (303). This advantage would allow those humans with the allele (or alleles) to survive under a particular selective pressure, and thus, the IBD susceptibility alleles would increase in frequency in the population. A balance would be achieved when the advantageous effect of the alleles matches the frequency and severity of the disease for which they predispose. Understanding how IBD susceptibility alleles provide a selective advantage would be useful for two reasons. One reason is that this understanding would contribute to our general understanding of human evolution and history. The second reason is perhaps more important: understanding the selective advantage of IBD susceptibility alleles will provide knowledge of the underlying physiologic process at a very fundamental level that would promote gene identification, unraveling disease pathogenesis, and thus suggest entirely new therapeutic approaches.

Is there any information that would allow us to speculate on the selective advantage provided by the IBD susceptibility genes? Such speculation should be built on several basic observations:

IBD is clearly genetic, common, and occurs in many different ethnic groups throughout the world. Therefore, a selective advantage is likely to account for its high frequency.

IBD is clearly a complex genetic trait and is likely to encompass a spectrum of many diseases that present with similar characteristics. Therefore, there are many steps affecting many pathways in IBD pathogenesis that could contribute to any selective advantage, and the advantage could be related to other diseases or other pathways not directly related to aberrant intestinal inflammation.

IBD has clearly increased dramatically in the developed world over the twentieth century and is now appearing

(or being recognized) with increasing frequency in the developing world. This indicates that some environmental factor or factors still operating in recent historical times could provide the selection pressure in the developing world. This further suggests that the incidence of IBD rises because the selective advantage is no longer acting against the selection pressure because the environmental selection pressure is disappearing.

The DZ twin rate for IBD is no greater than the sibling recurrence risk, suggesting that the environmental factors for IBD susceptibility affect the entire population. That is, the environmental factors are probably ubiquitous, rather than varying dramatically in frequency between families within a population or over a short time period (the few years of childhood).

IBD is clearly an inflammatory and immunologic disease of the gut, suggesting that environmental factors that provide the selection pressure may have operated in the gut.

On the basis of these observations, the authors have proposed the following hypothesis: the genetic variation that predisposes to the various forms of IBD provided a selective advantage in the form of mucosal immunoprotection in an unsanitary world (282). Effective public sanitation is a development of modern civilization, and we propose that the development of such sanitation removes the selective advantage of IBD susceptibility alleles. However, the mucosal immunoprotection provided by IBD susceptibility alleles is still primed genetically in those with the *IBD* genes, armed, if you will, to defend the organism. Thus, we have proposed that when IBD predisposing alleles are not adequately used in mucosal defense, the situation of the developed world, either (1) later exposure to an infectious agent would result in hyperstimulation of the immune response and subsequent chronic inflammation (analogous to paralytic polio, which occurs when infection occurs after early infancy), or (2) failure of exposure to a potentially injurious agent would leave the gut immunologic system in a continuously primed state and thus lead to subsequent dysregulation, for example, an autoimmune reaction that results in the diseases we recognize as UC and CD (282,304).

This hypothesis could provide a possible explanation for the relatively higher frequency of IBD in the Jewish population (282). IBD appears to be highest in frequency in Ashkenazi Jews (i.e. Jew whose origin is middle and eastern Europe), suggesting that the selective factor or factors had their greatest influence after the Ashkenazi/Sephardic division, coinciding with the historical division of Europe and the Mediterranean between the Christian and Islamic kingdoms (86). However, the greatest frequency of IBD is distributed in those Ashkenazi Jews whose origin is in middle Europe (97,98) and is similar to the distribution of Tay-Sachs gene carriers (305). Historically, countries in middle Europe imposed the greatest ghetto urbanization on Jews, perhaps leading to the greatest overcrowding and to the consequent

greatest defects in sanitation. This situation eased when the Ashkenazi Jews were invited to settle in eastern Europe with less pressure from ghetto urbanization, that is, Poland, Ukraine, and Russia. More individuals that are Tay–Sachs heterozygotes or IBD patients come from middle as opposed to eastern Europe (98,305). The lower frequency of IBD in Israel when compared with that of western Europe or the United States could possibly result from the more developing nature of that society. Regardless, if the specific details of this hypothesis are correct, it will be important to determine, if indeed, a genetically hyper-responding mucosal immune system is responsible for the susceptibility to IBD.

## 68.10 GENE IDENTIFICATION

### 68.10.1 Genomewide Linkage Studies

The epidemiologic evidence demonstrating a major genetic contribution to IBD susceptibility has resulted in several genome scans for IBD susceptibility loci examining linkage to CD, UC, or IBD combined. Specific genomic regions identified by the whole genome approach have been further tested by yet more laboratories in more targeted linkage studies. This international effort is noteworthy within the study of the genetics of complex diseases in that several susceptibility loci for IBD have been identified by more than one laboratory.

Table 68-8 shows the major IBD susceptibility loci demonstrated by linkage studies. Consensus has been reached by an international consortium on IBD genetics (International IBD Genetics Consortium) that the genomewide approach provides evidence for susceptibility loci for IBD on chromosome 16q12 (IBD1) and on chromosome 12 (IBD2). Further agreement has been reached by some of the members of this consortium that there is evidence for loci at or near the MHC on 6p21.3 (IBD3), at 14q11–12 (IBD4), 5q31 (IBD5) and 19p13 (IBD6). More loci likely exist; some have

probably been detected by this effort already. If a cut-off is arbitrarily set at a logarithm at OR (LOD) = 2 or at  $p < 0.001$  or at replication in two studies, then additional tentative loci may also have been identified at 1p36 (IBD7) and 3p26 (IBD9), and on chromosomes 4, 5, and 7. Complete reviews of linkage results are available (125,337).

Even though some of these linkage results will represent false-positive findings incurred during the analysis of the genome screen data, clearly these results already support the following ideas: (1) there are multiple susceptibility loci for IBD, (2) CD and UC share some loci in common and do not share other loci, and (3) some of these loci interact, and (4) different loci play different roles in the IBD susceptibility of different populations.

### 68.10.2 Chromosome 16 (IBD1, OMIM #266600)

The chromosome 16 locus was the first locus to be identified by the whole genome approach (306), was quickly confirmed by the authors (314), and currently has the strongest experimental support worldwide. A two-point LOD score of 2.04 was observed for marker D16S409 in an initial family panel with 25 sibling pairs affected with CD with no known cases of UC (CD-only families) and in a second panel of 53 IBD families (306). This result was confirmed in an independent sample the same year with a peak multipoint LOD score (MLS) of 2.1 at D16S411 (314). After stratifying based on Jewish ethnicity, the MLS increased to 2.4 for the non-Jewish families and decreased to lack of evidence for linkage in the Jewish families. This suggested that the chromosome 16 region contained a susceptibility locus for CD that is important for the non-Jewish population. Fine-mapping to a 1-cM resolution has resulted in a MLS of  $Z = 2.81$  ( $p = 0.0003$ ) at D16S416–D16S3117 (312). Linkage of this region was also observed in families with UC only (NPL = 2.02,  $p = 0.02$  at D16S3120) but, surprisingly,

TABLE 68-8 Susceptibility Loci for Inflammatory Bowel Disease

CD, Crohn's disease; IBD, inflammatory bowel disease; TNF, tumor necrosis factor; UC, ulcerative colitis.

<sup>a</sup>First reference is the initial report.

not in families with both CD and UC subjects (mixed families) (313).

In an effort to combine the observations of the various laboratories worldwide in a single nonparametric analysis, members of the International IBD Genetics Consortium combined genotype data for the same six markers broadly spanning the IBD1 region (308). A total of 581 families (382CD only, 91UC only, 108 mixed) had data available for both parents and at least two affected sibpairs. An MLS of 5.2 for this locus was observed in CD but not in UC. This is among the highest LOD scores observed in any complex trait and demonstrates the importance of the study of a large number of families in order to detect modest genetic effects by linkage. Approximately 10–15% of the susceptibility to CD was estimated to be accounted for by this locus. The interval containing multipoint evidence within 1 LOD of the peak spans less than a 10-cM region between D16S753 and the interval between the markers D16S411 and D16S419.

An extensive and elegant positional candidate approach by Hugot et al. (283), as well as a candidate gene approach by Cho et al. (338), has led to the identification of the *CARD15/NOD2* gene as the susceptibility gene for IBD at this locus (see below).

The existence of a second IBD gene within the initial linkage region has been proposed by Hampe et al. (334) based on their observation of other linkage signals on chromosome 16 after stratification on the presence or absence of one of the *CARD15* risk. One of these peaks contains the *CARD15* gene, but another region centered around D16S3068, 25 Mb from *CARD15*, appears in their analysis to confer IBD risk independently of the *CARD15* gene. The designation IBD8 (OMIM %604519) has been assigned to this locus. The authors of this chapter, as well as Van Heel et al., confirmed linkage of CD to chromosome 16 in the absence of the three major *CARD15* variants between D16S514 and D16S515 ( $p = 0.0007$ ) (331,339).

### 68.10.3 Chromosome 12 (IBD2, OMIM %601458)

The chromosome 12 locus (IBD2) was the second region to be identified by a whole genome approach (316). A two-point LOD score of 5.47 ( $p = 2.66 \times 10^{-7}$ ) was observed in a set of 186 sibpairs from CD only, UC only, and mixed families at the marker D12S83. An association between a “4-1-3” haplotype constructed with markers D12S83, D12S1662, and D12S1655 and UC was observed in further work using the transmission disequilibrium test (TDT) (340). Both the linkage and association findings have been replicated in North American studies: one observing an association to the same marker D12S83 in both CD and UC families using the TDT (318), and one to a marker 14cM away at D12S85 in CD families (322). The International IBD Genetics Consortium observed a greater linkage of UC to this region

rather than CD (308,320). Jewell et al. have proposed that this locus contributes more to UC than to CD (320); however, Lesage et al. disagree (321,341). A third possibility in this debate is that there may be two loci in this region, one for CD and one for UC.

No gene for IBD2 has been identified thus far; a few candidate genes have been tested for association to IBD, CD, or UC based on their location within the IBD2 region, and negative results have been reported for interferon gamma (IFNG) (342), keratin 8 (KRT8) (343), and the natural-resistance-associated macrophage protein (NRAMP2) (344).

### 68.10.4 Major Histocompatibility Complex (MHC; IBD3, 6P21.3)

On the basis of the hypothesis that IBD pathogenesis may involve immunoregulatory factors, candidate genes within the MHC on chromosome 6p21.3 have long been tested for IBD susceptibility with conflicting results (see later). However, linkage of the region to IBD has been established. In a study of the sharing of MHC haplotypes, which allowed the delineation of identity by descent of all markers (323), linkage to MHC was observed using several nonparametric methods: (1) an increased number of sibpairs sharing one or more haplotypes ( $p = 0.004$ ), (2) an increased mean proportion of sharing between concordant affected ( $p = 0.002$ ) and concordant unaffected ( $p = 0.03$ ) pairs, along with a decreased proportion in discordant pairs ( $p = 0.007$ ), (3) a significant linear relation between the similarity of phenotype between members of a sibpair and the proportion of their shared haplotypes by regression analysis ( $p = 0.00003$ ), and (4) an increased sharing between pairs more distantly related than sibpairs ( $p = 0.001$ ). Linkage was also observed in this region in a genome scan by the same investigators (319). Further support for linkage of the MHC region to IBD has been observed by additional laboratories following the systematic mapping approach: (1) an MLS of 4.2 for D6S461 in 284 German families (152); (2) a peak nonparametric LOD score of 2.3 ( $p = 0.0026$ ) for D6S1017, with other NPL scores higher than 2 for nearby markers in 158 Canadian families (327,345); (3) a peak nonparametric LOD score of 3.04 near D6S291 in 234 UK families (324); and (4) an MLS of 5.91 for male affected only in 428 European families (325).

Genes at this locus have been tested and several associations reported (see later). The fact that there are numerous candidate genes for IBD within the MHC will make finding-specific causal variants problematic.

### 68.10.5 Chromosome 14 (IBD4, OMIM %606675)

Evidence for linkage between CD and the marker D14S261 has been observed in a study of 46 families

from Los Angeles (MLOD 2.8,  $p = 0.0002$ ) (207) and of 62 families from Pittsburgh (MLOD 3.6) and to the general region of this marker in a third study of 89 Flemish families (D14S80, NPL 2.41,  $p = 0.008$ ) (329). An MLOD of 2.36 ( $p \leq 0.01$ ) was observed by the International IBD Genetics Consortium in 733 IBD families (279). This linkage was observed only in those families, in which at least one sibling smoked, suggesting that IBD4 interacts with this environmental factor. No gene for this locus has been identified to date.

### 68.10.6 Chromosome 5 (IBD5, OMIM %606348)

Evidence for linkage to the region D5S393–D5S673 has been observed in Jewish CD-only families (319) and in CD families with early-onset disease (MLOD 3.9) (327). This region is syntenic to a mouse region implicated in the dextran-sulfate-induced colitis rodent model (346) and maps to a cytokine gene cluster containing many candidate genes for IBD. Rioux et al. (347) applied a systematic linkage disequilibrium (LD) mapping approach in order to find the causal variation with this linkage region by constructing a dense genetic map composed of both microsatellite and single-nucleotide polymorphism (SNP) markers across the 18-cM region and identified a 250-kb-long haplotype block conferring susceptibility to CD. The LD across this block was so strong, however, that they were unable to identify causal variation for CD within the *SLC22A4*, *SLC22A5*, or *PDLIM3* genes that lie on this block. The association of this block to CD was subsequently confirmed in Germany (292:212 transmitted:nontransmitted in IBD trios,  $p = 0.0002$ ) (348) and in Britain (23% in CD compared with 14.7% in control,  $p = 0.0002$ , RR 2.0 95 CI 1.4–2.8 for homozygote; 163:114 transmitted:nontransmitted,  $p = 0.0066$ ) (349,350). Negoro et al. also tested for interactions between the IBD5 CD haplotype and CARD15 mutations and demonstrated that IBD5 and CARD15 independently contribute to CD.

### 68.10.7 Chromosome 19P13 (IB6, OMIM %606674)

Significant linkage of IBD to the marker D19S591 with an MLS of 4.6 was first observed in Canadian sibpair families (327). Some evidence for linkage to this same marker has also been reported by another study (328) (two-point LOD score 1.6,  $p = 0.0067$ ) and to a neighboring region at D19S1034–D19S586 by a third group (multipoint  $p = 0.0059$ ) (310). It is important that the linkage region in these studies spans almost the entire chromosome, so that gene finding for this locus will be difficult. Van Heel et al. (331) tested for interactions between this locus, CARD15 mutations, and IBD5 and reported greater linkage in subjects that did not have CARD15 mutations (D19S217, LOD 2.9,  $p = 0.0001$ , for

subjects without CARD15 mutations compared to LOD 0 for subjects with CARD15 mutations) and for subjects that did have one or two copies of the IBD5 CD susceptibility haplotype (D19S425, LOD 2.4,  $p = 0.0005$ ).

Because the linkage evidence to date covers most of chromosome 19, there are many possible candidate genes for this locus. The association of ICAM1 and CD and UC has been observed (51), and Low et al. (333) have proposed that ICAM1 is the susceptibility gene in this region (see later).

### 68.10.8 Chromosome 1P36 (IBD7, OMIM %605225)

Two studies have observed evidence for linkage to the D1S2670–D1S2682 region (MLOD 2.65,  $p = 0.0002$ ) (310) and (MLOD 2.08) (152). Families with linkage to this region also show greater linkage to IBD1, suggesting that this susceptibility locus interacts with IBD1 (310). Further narrowing of this region to 130 kb near D1S2697 and D1S3669 has been accomplished by homozygosity mapping in a collection of American Iraqi Chaldean families with IBD (332). Because both CD and UC are observed in these families, these authors have proposed that this locus determines a generic susceptibility to IBD, with the concomitant inheritance of IBD1 than determining CD.

### 68.10.9 Chromosome 3P26 (IBD9, OMIM %608448)

A suggestion of linkage to the region D3S1076–D3S1573 in CD-only families was also observed in the same study that reported the initial linkage to chromosome 12 (242,316). With further fine mapping, a peak single-point linkage to CD has been observed by this group at marker D3S3521 (LOD 3.5,  $p = 0.00003$ ), with the support region (LOD within 1 of the peak) spanning D3S11–D3S3559 (351). This result was confirmed by Hampe et al. (D3S1304, MLOD 1.65) (336) and by Duerr et al. (D3S1297, MLOD 3.39,  $p = 0.000052$ ) (335). A candidate gene has yet to be identified for this locus.

### 68.10.10 Meta-Analysis Across All Genome Scans

The field of the genetics of IBD is one of the leading fields in the genetics of complex traits in that there has been replication of several genomic regions. Nevertheless, many of the loci identified have not been reproduced across studies. This is somewhat expected because (1) there are differences in sampling between the various centers conducting these studies worldwide; (2) reliable detection of linkage requires a sample size that is larger than the usual linkage study performed in IBD genetics (~100 sibpairs) (122,352); and (3) even larger sample sizes are required for confirmation of a linkage result by a second study.

The effort of the International IBD Genetics Consortium to combine linkage studies and genotype large numbers of individuals with the same microsatellite markers has been one strategy to overcome these problems. Another strategy has been to combine data from many linkage studies. The genome search meta-analysis method (GMSA) divides the genome into 120 bins 30 cM in size and ranks the evidence of linkage for that bin in each genome scan (353,354). When applied to the genome scans for IBD susceptibility loci, IBD3 emerges as the most significant locus for IBD and CD (345,355,356), showing that a locus may attain greater significance in a combined data analysis than is apparent in a single-genome scan. The GMSA of four genome scans by Williams et al. ranked IBD1 next in importance for IBD, and IBD5 and IBD1 next for CD, and the GMSA of van Heel et al. ranked IBD1 and IBD6 for CD.

## 68.11 CANDIDATE GENE STUDIES

In the candidate gene approach, genetic variants are tested based on a prior hypothesis regarding the role of that gene or gene product in the pathophysiology of the disease. Such a hypothesis may be based on evidence from clinical observation or physiologic studies of affected individuals (in vivo studies), from studies of known disease-related processes (in vitro studies), from animal models of disease (transgenic construction or targeted disruption), and from the effects of drugs or chemicals on disease in either humans or animals (pharmacogenetic studies). For IBD, possible candidates could be selected from genes involved in the regulation of the balance between TH1 and TH2 cells; the response of humans to gut flora, particularly the innate immune system; and the release of cytokines during the immunologic destruction and healing of the intestinal mucosa.

### 68.11.1 The Major Histocompatibility Complex (MHC; IBD3)

The MHC on chromosome 6p21.3 is the most important genomic region for innate and adaptive immunity, containing genes involved in the regulation of the immune system and in antigen processing and presentation. Classically, the MHC contains 224 genes identified within a 3.6-Mb region (357); however, accumulating evidence supports the idea that the cluster of genes important for immune pathways spans 7.6 Mb and contains 421 genes (282 expressed, 139 pseudogenes) (358). Because the MHC is a candidate region for most, if not all, diseases with dysregulation of the immune system as the possible underlying pathophysiology, the MHC has long been studied in IBD genetics. However, assigning the specific role of a specific gene to the pathophysiology of IBD has been hampered by several factors: (1) the MHC includes the most polymorphic human proteins known, the HLA class I and class II molecules, and some of these proteins

have more than 100 allelic variants; (2) LD extends over great distances throughout this region such that associations can be observed with variants that are not located in the gene actually related to IBD pathophysiology; and (3) the size of many of the studies reported have not been large enough to demonstrate adequately the small effects of some of these genes and so have been difficult to replicate by other investigators.

**68.11.1.1 The MHC Class II Region.** In general, the class II molecules are dimeric, with an  $\alpha$ -chain and a  $\beta$ -chain that form a groove for presenting an extracellular antigenic peptide to CD4<sup>+</sup> T cells. The three class II molecules are HLA-DP, HLA-DQ, and HLA-DR. In each case, the  $\alpha$ - and  $\beta$ -chains are encoded by *A* and *B* genes, respectively. For HLA-DR, there is an invariant *HLA-DRA* gene and up to three distinct and highly polymorphic *HLA-DRB* genes. One of these *HLA-DRB* genes, *HLA-DRB1*, is present in all individuals and is the most polymorphic. The study of *HLA-DRB1* alleles has been an important tool in the study of the role of class II genes in IBD. Serologic methods identify several HLA-DR types and subtypes, and were used in the older studies, whereas molecular methods reveal even more subtypes at the nucleotide level and are the preferred techniques today. A meta-analysis of 29 studies reporting HLA-DR or HLA-DQ frequencies in CD and UC patients and in controls has been published (359). The results of this analysis and of recent association studies using molecular methods are summarized in Table 68-9.

The authors have identified an association between the combination of HLA-DR1/HLA-DQ w5 alleles and CD in whites in the United States and HLA-DR2 and UC (367). The association between HLA-DR1 and CD has also been observed in France (360) and in The Netherlands (373). Associations with HLA-DR3 and CD and DR13 and UC have been observed in Italy (374). Further molecular typing revealed that, of all the DR1 alleles, only the *HLA-DRB1\*0103* allele, and not other DR1 subtypes, was associated with CD as well as UC (see Table 68-9) (365). This finding pointed to the importance of molecular typing over serologic typing as the means to clarifying the associations between class II alleles and IBD; an example of the associations between IBD and HLA alleles typed using molecular methods in one of the largest studies to date is given in Table 68-10. An association between CD and *HLA-DRB1\*0405* ( $p = 0.001$ , OR 2.02) and *HLA-DRB1\*0410* ( $p = 0.002$ , OR 4.79) has been observed in Japan (375). An association between *HLA-DRB1\*0103* and UC has been reported in the Japanese population (242) and in Britain (119,363). In UC patients with colectomy, *HLA-DRB1\*0103* is associated with a shorter time to surgery, as determined by Kaplan–Meier survival analysis (9 months compared with 5.2 years,  $p = 0.002$ ), suggesting association with a more aggressive UC. Roussomoustakaki et al. observed that this allele is associated with extensive UC, extraintestinal manifestations of UC, or with some complications of UC (mouth ulcers,

arthritis, or uveitis). In Britain, HLA-DRB1\*0103 has also been associated with the extraintestinal manifestation of peripheral arthropathy in IBD patients when compared with controls (376). The authors have further observed that the association of DR2 with UC was due to the HLA-DRB1\*1502 allele (365). In addition, a rare HLA-DRB1\*0103-DQA1\*0501-DQB1\*0301 haplotype was dramatically associated with IBD with an

OR of 6.6, and a more common DR1 haplotype, HLA-DRB1\*0103-DQA1\*0101-DQB1\*0510, was also associated with IBD. This result suggested that an interaction between HLA-DR and HLA-DQ may determine the extent of disease risk.

A new association at another MHC class II locus, HLA-DP, has been observed; the common HLA-DPB1\*0401 allele confers a modest risk for CD (365).

**TABLE 68-10 Summary of Class II Associations with Crohn's Disease (CD), Ulcerative Colitis (UC), or Both Inflammatory Bowel Disease (IBD)**

Class II Allele	Disease or Haplotype	% Affected	%Control	<i>p</i>	OR
IBD	DRB1*0103	8.3	2.2	0.001	4.6
–CD		7.9	¢¢	0.002	4.4
–UC		8.9	¢¢	0.001	4.9
IBD	DRB1*0103- DAQA1*0501- DQB1*0303	2.8	0.4	0.034	6.9
IBD	DRB1*0103- DAQA1*0101- DQB1*0501	6.4	2.2	0.007	3.5
UC	DRB1*1502	11.9	4.7	0.006	2.6

From Trachtenberg, E. A.; Yang, H.; Hayes, E.; et al. HLA Class II Haplotype Associations with Inflammatory Bowel Disease in Jewish (Ashkenazi) and Non-Jewish Caucasian Population. *Hum. Immunol.* **2000**, 61, 326–333.

\*Genes numbers from Entrez Gene, National Center for Biotechnology Information, National Institutes of Health, [www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=gene](http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=gene). OMIM numbers from the On-line Mendelian Inheritance in Man database, [www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=omim](http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=omim).

The HLA-DRB1 association has also been confirmed by a different method, genotyping DNA pooled from CD patients and controls and measuring differences in the allele frequencies (rs1729, major allele frequency 0.70 in CD patients and 0.90 in controls,  $p = 3.02 \times 10^{-9}$ ) (377).

The results summarized in Tables 68-9 and 68-10 clearly point to a role for the MHC class II genes in the pathogenesis of IBD. However, three lines of evidence suggest that the contribution of the MHC to IBD is likely to consist of more than that provided by the class II region: (1) There is some evidence of association to other MHC genes (see later). (2) Although some investigators have confirmed associations to the same class II alleles, others have observed associations to other class II alleles, particularly when studying other populations. This suggests that at least some MHC class II alleles are not the IBD susceptibility alleles but are in LD with susceptibility alleles. (3) The results of two genome scans (319,326) raise the question as to whether the peak linkage to IBD in this region may be several centimorgans telomeric from MHC and the result of the third (327) suggests that the peak may be centromeric. (4) The magnitude of the linkage effect is not explained by the relatively modest associations of MHC class II alleles heretofore observed. This evidence suggests that further fine LD mapping of the MHC and IBD is also warranted. Strategies to unravel the role of the potentially multiple MHC genes involved in the susceptibility to IBD are (1) to carry out this fine mapping using both case-control and family-based association tests and to follow leads that are positive with both methods, and (2) to examine the contribution of each locus in isolation from the others by methods that stratify the genotyping data at one locus with respect to another locus.

**68.11.1.2 NOTCH4 (Gene Id #4855).** A preliminary example of such a fine-mapping effort has revealed

further susceptibility loci in MHC class III region around NOTCH4. The NOTCH4 gene is a homolog of the *Drosophila* Notch gene, and in humans, is located in the MHC class III region close to the border with the class II region. The function of human NOTCH4 is not currently known, but the family of Notch proteins is involved in the control of cell fate decisions during development (378) including hematopoiesis (303) and gut epithelium (379). Notch receptors and ligands are also expressed in the thymus, and the overexpression of Notch1 in a mouse transgenic strain directs CD4<sup>+</sup> CD8<sup>+</sup> precursors to the CD8 lineage (380). Authors have observed that an allele of NOTCH4 is associated with CD in Ashkenazi Jews in both a case-control study and a family-based study by TDT (381). This genetic association is independent of the HLA-DRB1 associations discussed earlier and supports the idea that multiple genes in the MHC may be determining IBD. In a study of well-characterized CD patients, the same allele was also associated with a subset of CD patients characterized by an earlier age of onset of CD and no expression of pANCA combined with a high expression of ASCA (44). These observations suggest that either NOTCH4 itself or a gene close by may also determine one of the subtypes of CD.

**68.11.1.3 Tumor Necrosis Factor (TNF, Gene Id #7124).** Tumor necrosis factor (TNF) is involved in the regulation of inflammation at many levels; of particular interest for IBD is the role of TNF in the recruitment of circulating inflammatory cells to local tissue sites and in granuloma formation. TNF is an important proinflammatory cytokine in CD (382), and its pivotal role in CD is prominent in mouse models of intestinal inflammation: a transgenic that increases TNF expression has colitis (383) and a TNF knockout reduces the ability of chemicals to induce colitis (384). TNF is also of interest in CD because

anti-TNF antibody is an effective treatment of moderate to severe CD (385). The genes for three members of the TNF superfamily, TNF, lymphotoxin alpha (*LTA*, gene #4049) and lymphotoxin beta (*LTB*, gene #4050) are located adjacent to each other at the border between the class III and class I regions of MHC (358,386). Several studies have observed an association between polymorphisms in this region and (1) changes in TNF expression (387–389), (2) altered immune response to infectious diseases (162,390–393), and (3) increased joint damage in rheumatoid arthritis (394). The association between IBD and variants in the TNF gene has been difficult to demonstrate, probably because the magnitude of the effect is small. However, in a large British case-control study, the C allele of the TNF-857C/T promoter polymorphism has been associated with IBD (534/587 were CC with IBD compared with 231/278 controls,  $p = 0.0014$ ), UC (280/304 were CC,  $p = 0.001$ ), and with CD patients who did not have NOD2 mutations (see later) (222/241 were CC,  $p = 0.0022$ ) (389). This result has been confirmed in Australia by TDT of 170 multiplex families (395). The British study found that blood from individuals with the TNF-857 CC genotype produced higher levels of TNF when stimulated by lipopolysaccharide (LPS); these authors also demonstrated that OCT1 bound to the TNF promoter with the T allele, not the C allele, and so proposed that the T allele of this variant allowed OCT1 to interfere with normal TNF transcription (389). Two observations suggest that genetic variation in the TNF region may also determine the course of disease in subsets of IBD: (1) a haplotype in the *LTA* region may be associated with a lack of response to anti-TNF therapy in a group of patients with moderate to severe CD (396); and (2) TNF microsatellite a is associated with the level of expression of ASCA antibody (397).

### 68.11.2 CARD15/NOD2 (IBD1; GENE ID #64127; OMIM \*605956)

Hugot et al. (398) applied the positional cloning approach in order to identify the gene causing susceptibility to IBD within the IBD1 locus. These authors began with a fine-map of 26 microsatellite markers spaced ~1 cM apart spanning the IBD1 locus, obtained a borderline TDT result with one allele of marker D16S3136, and sequenced the region, identified SNPs, and genotyped CD patients for these SNPs. These SNPs in the surrounding region were in LD with each other, and several were associated with CD to varying degrees. At the time of their study, no genes had been identified in this region, but GRAIL analysis predicted a gene in the region, and the existence of this gene was then confirmed by clones sequenced from a human leukocyte cDNA library. Three SNPs altered amino acids in this predicted protein, R675W (SNP8), G1881R (SNP12), and 980-frameshift-981X (SNP13) were associated with CD; the pedigree disequilibrium test (PDT) was most significant for SNP13

( $p = 6 \times 10^{-6}$ ). The relative risk for CD for being a heterozygote with one of these mutations was 3; for being a homozygote, 38; and for being a compound heterozygote, 44. The frequency of one of these three mutations is 0.07 in controls, 0.05 in UC patients, and 0.29 in CD patients.

Simultaneously with the fine-mapping study by Hugot et al., Ogura et al. were following a candidate gene approach based on the discovery that the mouse *Nod2* gene, a member of a gene family that contains a caspase recruitment domain (CARD) and that activates NF-kappaB (399), mapped to the human IBD1 locus. *Nod2* is now known as *CARD15*. By sequencing this gene in CD patients, these authors identified the same frameshift mutation observed by Hugot et al. and demonstrated an association of the frameshift mutation to CD using both the TDT and case-control study designs (338). NF-kappaB signaling was defective in cells coinfecting with NF-kappaB reporter constructs containing human *CARD15* sequence with the frameshift mutation. This observation suggested that mutations in *CARD15* alter response to bacterial antigens.

The Hugot et al. and Ogura et al.'s papers were published side-by-side in the journal *Nature* and together gave convincing evidence that *CARD15* was the susceptibility gene for CD. Their result has been confirmed by many investigators (18,118,400–409). The identification of *CARD15* as a CD susceptibility gene represents the final argument that CD is a genetic disorder.

All the three predisposing mutations were found on the same background haplotype that included a fourth SNP, SNP5 identified by Hugot et al. This observation suggested the possibilities that CD susceptibility required (1) the combination of SNP5 with one of the other predisposing SNPs or (2) some other unidentified variant in LD with SNP5. The authors of this chapter observed, in contrast to Hugot et al., that this background haplotype alone, without one of the three predisposing mutations, was associated with CD in Ashkenazi Jewish CD subjects (OR = 3.13,  $p = 0.023$ ) (339). Sequencing of this haplotype revealed a new *CARD15* variant, JW1 (IV8+158), such that the *CARD15* SNP5-JW1 haplotype showed exhibited increased risk (OR = 5.75,  $p = 0.0005$ ) for CD and the highest population-attributable risk (15.1%) for CD among the reported CD susceptibility SNPs in Jews, as compared with non-Jews. Investigators in Israel have reported an association between the *CARD15* G908R SNP (SNP8) and a younger age of CD onset (25% pediatric CD patients compared with 9% of adult CD patients,  $p = 0.003$ ) (410). *CARD15* mutations are associated with CD in Israel (411). In New York, a higher frequency of *CARD15* mutations was found in Ashkenazi Jewish subjects from multiplex families with CD from Central (44%) compared with Eastern (24%) Europe origin and in Sephardic/Oriental Jews compared with controls (412).

None of the three major *CARD15* mutations was observed in 483 Japanese CD patients, and sequencing

portions of the exons 4, 8, and 11 from the *CARD15* gene in 96 patients did not demonstrate any variants of consequence (288); these SNPs were also absent in 126 Korean CD patients (413) and in 63 Chinese CD patients (414). These observations suggest that *CARD15* does not play a major role in CD susceptibility in Asia. Genotyping and sequencing also failed to demonstrate an association between *CARD15* and CD in a patient sample from Tunisia (415). Significantly lower frequencies of *CARD15* mutations have been observed in black and Hispanic children with CD (416).

Several reports have explored the relationship between *CARD15* mutations and CD clinical phenotypes. Work by the authors of this chapter using univariate analysis demonstrated that the three CD susceptibility variants were significantly associated with fibrostenosing disease (46% of patients with fibrostenosing disease carried at least one of the three variants compared with 24% of patients without fibrostenosing disease (OR 2.8, 95% CI 1.6–5.2) (118). Multivariate analysis showed that the primary association was with the fibrostenosing disease rather than small bowel disease. CD patients with two *CARD15* mutations are characterized by a younger age at onset of disease (16.9 years compared with 19.8 years,  $p = 0.01$ ), a stricturing phenotype (53% compared with 28%, OR 2.92,  $p = 0.00003$ ), and less-frequent colonic involvement (43% compared with 62%, OR 0.44,  $p = 0.003$ ) than CD patients with no *CARD15* mutations (407). Investigators in Italy observed that CD carriers of at least one of the three major *CARD15* variants were younger and more likely to have an ileal localization of disease, stenosing pattern, previous surgery, and ASCA expression (400). The association between *CARD15* mutations and ileal disease either with fibrostenotic complications or with younger age of onset was observed by others (18,417,418).

The identification of *CARD15* as a CD susceptibility gene immediately focused attention on the role of the innate immune system in developing colonic inflammation. The *CARD15* protein binds muramyl dipeptide that originates from bacterial peptidoglycan (419); peripheral blood mononuclear cells from individuals homozygous for the *CARD15* L1007fsinsC (SNP13) fail to respond to muramyl dipeptide, as measured by activation of NF- $\kappa$ B (420). Muramyl dipeptide induced secretion of IL8 in these cells and upregulates the TNF and IL1- $\beta$  secretion induced by other Toll-like receptor ligands (421), but these effects are abolished in cells from CD patients with *CARD15* L1007fsinsC (SNP13). Mice with targeted disruption of the *CARD15* gene (Nod2-/- knockout) showed no overt intestinal inflammation but were sensitive to bacterial infection through oral delivery, suggesting that *CARD15* is important for intestinal immunity (422). The observation that *CARD15* is expressed in Paneth cells at the base of the small intestinal crypts supports this role (423), because Paneth cells secrete antibacterial substances in response to bacteria (120,424). The role for *CARD15* acting as

an antibacterial factor is supported by the observation that intestinal epithelial cells (CaCo2 cell line) stably transfected with a wild-type *CARD15* construct were able to prevent invasion by *Salmonella typhimurium* but not with a construct carrying the *CARD15* L1007fsinsC insertion (425).

### 68.11.3 SLC22A4/SLC22A5 (IBD5; GENE IDs #6583 & 6584; OMIM 604190 & 603377)

As described earlier, high-resolution linkage LD mapping of the IBD5 locus led to the identification of a 250-kb haplotype conferring CD susceptibility, but that the LD across this region was too high to allow determination of the specific gene with this region that was involved in CD (347). Subsequently, 10 novel SNPs were identified by resequencing the five genes within this interval, and two of these were predicted to have functional effects, an L503F amino acid substitution in the solute carrier family 22 (organic cationic transporter) member 4 gene, *SLC22A4*, and a -207G->C transversion disrupting the heat shock element in the promoter of the *SLC22A5* gene (426). A T-C haplotype of these two SNPs were at a higher frequency in CD patients compared with controls (54% versus 42%,  $p = 0.0003$ ) and had a population attributable risk of 19% for heterozygotes and 27% for homozygotes. This haplotype does not confer risk to UC. These two SNPs were also associated with CD when they were located on other IBD5 haplotypes that were not the CD susceptibility haplotype (14.3% in CD compared with 9.8% in controls,  $p = 3.5 \times 10^{-9}$ ), arguing that these two SNPs, rather than nearby alleles, conferred CD susceptibility. Both proteins were expressed in human colon. The *SLC22A4* L503F SNP “F” allele decreased the sodium-dependent carnitine transport and carnitine affinity of this protein. The CD-associated variant in the promoter of *SLC22A5* was shown to disrupt formation of a protein complex by gel shift assay and to reduce transcription in a luciferase reporter assay. These authors have proposed that, because carnitine mediates fatty acid oxidation and inhibition of fatty acid evokes colitis, impaired carnitine transport may be the mechanism that *SLC22A4* confers CD susceptibility (427). Combination of the *SLC22A4/A5* T-C haplotype with one or more of the three common *CARD15* variants confers a 7.5-fold increased risk for CD ( $p = 9 \times 10^{-8}$ ) (49).

When taken together, this combination of genetic and cellular observations suggest that the *SLC22A4/A5* T-C haplotype confers CD susceptibility and comprises the functional variation of the IBD5 locus.

### 68.11.4 DLG5 (GENE ID #9231; OMIM 604090)

IBD was linked to the region D10S547–D10S192 (MLOD 2.07,  $p = 0.0033$  at D10S548) (152). With stages of fine-mapping, an association with CD was detected at

D10S201 ( $p < 0.01$ ), then with an SNP, rs1344966 (CD,  $p = 0.002$ , IBD,  $p = 0.0006$ ) (428). Of the two genes in the region, DLG5 and KCNMA1, the association signal was confined to DLG5, discs, large homolog 5 (so named because of its homology with a gene in *Drosophila*). SNP rs1248696, R30Q, is overtransmitted to CD patients by the TDT (82 transmitted:54 nontransmitted,  $p = 0.004$ ), suggesting that DLG5 is associated with CD. The R30Q SNP was associated in one experiment from a case-control study (11% or 73/591 in CD compared with 5.9% or 24/380 in controls,  $p = 0.003$ ) but not in a second, and was significantly associated in a TDT (355). These results support the hypothesis that the haplotype block containing R30Q is associated with CD. A study from Scotland (429) and another study from Germany (430) did not confirm this association. A weak association of CD to DLG5 was observed in Japan, but the R30Q SNP was not (431), suggesting this gene may be important for CD in Japan but that different variants have arisen in this ethnic group.

### 68.11.5 ICAM1 (IBD6?; GENE ID #3383; OMIM 147840)

Intercellular adhesion molecule 1 (ICAM1, CD54) is involved in one of the several steps of the normal capture and migration of leukocytes from the blood stream to the site of inflammation (432,433). Several observations suggest that ICAM1 plays a direct role in IBD: (1) In mucosa taken from IBD patients and controls, a massive infiltration of ICAM1-positive cells has been correlated with the amount of inflammation in IBD (434). The concentration of ICAM1 is significantly elevated in CD and UC patients and is also higher in active UC compared with inactive UC (435). (2) Plasma-soluble ICAM1 is also higher in patients with active UC, pouchitis, and CD (436). (3) Anti-ICAM1 treatment of rats reduces intestinal inflammation in the acetic acid-induced model of colitis (437). (4) Antisense ICAM1 oligonucleotide prevents colitis in dextran-sulfate-induced mice (438) and reduces inflammation and leukocyte adherence in indomethacin-treated rats (439). The authors observed that the frequency of the "R" allele of the ICAM1 G241R polymorphism was higher for the ANCA-negative UC and for ANCA-positive CD subsets of disease but not for CD or UC as a whole when compared with controls (440), suggesting that this polymorphism determines the disease course of subsets of IBD. An association of the ICAM1 G241R SNP and UC and the K499E and both UC and CD has been reported in Germany (e.g. R241, controls: 9%, UC 16%,  $p = 0.024$ , CD not significant) (441) and of the ICAM1 K469E in Italy (e.g. E/E genotype, controls, 11%, IBD 24.9%) (442) and Japan (controls: 59.5%, IBD: 63.0%,  $p = 0.0025$ ; CD: 65.2%,  $p = 0.0056$ ; UC, 61.7%,  $p = 0.017$ ) (443). British investigators have observed an association between the

ICAM1 K/K genotype and CD (control 29.4%, CD 39.9%,  $p = 0.0096$ ) and have proposed that the ICAM1 gene is the susceptibility gene for the IBD6 locus (333). A negative result was reported for ANCA-positive UC (360,441), but it should also be noted that the method of ANCA determination is not uniform on both sides of the Atlantic. Italian investigators have reported that the ICAM1 K469E polymorphism is associated with a greater extent of CD and with penetrating disease behavior (444), and British investigators have reported that the G241R is associated with fistulizing disease (21.8% versus 10.0%,  $p = 0.03$ ) (333).

These observations are very suggestive that the common ICAM1 G241R and K469E amino acid variants are associated with CD and UC; however, the linkage region on chromosome 19 is very broad and the conclusion that ICAM1 is the IBD6 susceptibility gene must remain provisional. Formal studies must address two issues: First, does the ICAM1 association account for the entire linkage signal? This question could be examined by stratifying the linkage signal on the presence and absence of ICAM1 polymorphisms. Second, are there other ICAM1 polymorphisms or an underlying haplotype structure that is associated with a greater IBD susceptibility than that observed with these two polymorphisms? This question could be examined by genotyping more variants in this gene and performing an analysis of the association of the haplotype structure with IBD.

### 68.11.6 Other Observed Associations

**68.11.6.1 Interleukin 1 Beta (IL1B, Gene Id #3553) and Interleukin 1 Receptor Antagonist (IL1RN, Gene Id #3557).** The interleukin 1 (IL1) family consists of three related proteins: interleukin-1-alpha (IL1A, Gene Id #6552), interleukin-1-beta (IL1B) and interleukin-1 receptor antagonist (IL1RN). The genes for all three proteins are located together on chromosome 2q14 but not within a region of linkage observed in a genome scan. IL1A and IL1B are cytokines with a wide spectrum of proinflammatory actions in many cell types, and IL1RA inhibits the action of IL1A and IL1B by blocking the interleukin 1 receptor (445). When these cytokines were measured in freshly isolated intestinal mucosal cells from IBD patients and controls, an imbalance in the ratio of IL1 to IL1RN was observed in both CD and UC patients, with the ratio correlating closely with the clinical severity of disease (446). This observation was confirmed using biopsies from the inflamed mucosa of IBD patients (447). Furthermore, removal of IL1RA by treating animals with anti-IL1RN or by gene knockout increases susceptibility to experimentally induced colitis (448). These observations support the hypothesis that an imbalance between IL1 and IL1 receptor antagonist is important in the etiology of IBD (445,449).

Several groups have observed an association between IL1RN and UC, with an increased frequency of allele 2 of an 86 bp variable number of tandem repeats (VNTR) polymorphism in intron 2 of IL1RN in UC (449,450). This increased frequency was observed in patients from the Los Angeles area, particularly in a subset of UC patients from the Ashkenazi Jewish population. Biopsies from IBD patients with this genotype have a slight reduction of IL1RN (447). These results suggest that genetic variation in the IL1RN may alter the ratio between interleukin 1 and its receptor antagonist and thus contribute to susceptibility to IBD. An association between polymorphisms in IL1RN has been observed in some but not all subsequent studies (19,451–454). Furthermore, some evidence supports the concept that IL1RN polymorphisms may also participate in determining the course and severity of IBD: (1) a significant association has been observed between two polymorphisms in the interleukin 1 beta gene (IL1B; variants at –511 in the promoter and in exon 5) and nonperforating CD but not with perforating-fistulizing disease (19), and (2) IL1RN allele 2 has a higher frequency in surgically treated UC patients compared with nonsurgically treated patients or controls (451). When taken together, the evidence supports an association between polymorphisms in IL1RN and both CD and UC; the differences in these reports may be due to sample size problems and differences between the ethnic groups studied in these reports.

**68.11.6.2 ATP-Binding Cassette, Subfamily B (MDR/TAP), Member 1 (ABCB1, Gene Id #5243, OMIM 171050).** This gene is also known as “multidrug resistance 1 (MDR1)” and “P-glycoprotein 170,” a transporter that pumps neutral and cationic hydrophobic compounds and acts to pump toxins back into the gut lumen (455). Early observations on mice with a targeted disruption of this gene suggested that loss of ABCB1 expression in intestinal epithelial cells leads to colitis (456). The MDR1<sup>–/–</sup> is currently studied as a mouse model for IBD (457,458). This gene was resequenced in IBD subjects, and the ABCB1 A893S/T SNP was associated with both CD and UC by case-control ( $p = 0.002$ ) and PDT ( $p = 0.0002$ ) in a large study from North America (459). The ABCB1 C3435T polymorphisms were also associated with UC in studies from Germany (460,461); however, this result was not confirmed by studies from Germany and Britain (462) and Greece (463). ABCB1 is located at suggestive linkage region on 7q21 and may account for this LS (464).

These results are very promising for the role of this gene in both CD and UC. Further work should address whether there are promoter or other SNPs that exert a greater susceptibility than or in addition to the MDR1 A893S/T and C3435T SNPs. In future, the combination of the human variability and the mouse model will provide a powerful tool for unraveling the pathophysiology of IBD represented by this gene.

**68.11.6.3 Interferon Gamma Receptor Subunit 1 (IFNGR1, Gene Id #3459).** Mutations in the IFNG receptor subunit 1 gene (IFNGR1) have been associated with impaired response to IFNG (121,465) and susceptibility to mycobacterial infection (466–468). The authors have observed an association between a polymorphism in this gene and the development of chronic pouchitis in UC patients who have IPAA surgery (469). This observation raises the intriguing possibility that this receptor plays a role in determining the course of severe forms of UC. This gene is located in a peak of linkage to IBD on 6q (319).

**68.11.6.4 Solute Carrier Family 11 (Proton-Coupled Divalent Metal Ion Transporters), Member 1 (SLC11A1, Gene Id #6556).** The *SLC11A1* gene is also known as the natural-resistance-associated macrophage protein 1 gene and may be an important gene controlling response to infection by pathogens, particularly to *Mycobacteria* spp. (364,470,471). An association has been observed between CD and a haplotype composed of two markers that flank *SLC11A1*, D2S434 and D2S1323 (3a) and CD and one allele of a *SLC11A1* promoter microsatellite (472). A negative result has also been reported (111).

Therefore, rapid progress is being made with gene identification for the IBDs. The linkage data clearly identify specific and several genetic loci as contributing to the etiology of IBD; nine loci have been identified, and more have been suggested from the current linkage data. Recently, the *CARD15* gene has been identified and has focused attention on the role of the innate immune system in the pathophysiology of IBD. Many more genes for innate immunity are currently being tested, for example, those in Toll-like Receptor pathways, along with genes based on other functional hypotheses and mouse models, and consensus will emerge on the role of these in the near future. Good evidence exists for the contribution of multiple genes in the MHC, in particular, HLA-DRB1 in the MHC class II region, as well as for *SLC22A5/A5*, *DLG5*, and *ICAM1*.

## 68.12 CLINICAL APPLICATION OF GENETIC INFORMATION

In general, the genetic information described here is not yet used in clinical practice. Typing for ANCA and ASCA is on the verge of utility in diagnosing CD versus UC and in clarifying the cases of “indeterminate colitis.” At the current time, genetic markers are not used diagnostically although the use of these is currently under discussion. As for the serum antibody markers pANCA and ASCA, they can be used in diagnosis. Even though they are found at increased risk in relatives, screening relatives clinically is not recommended because there is no recognized intervention. Counseling is based on empiric risks, which were reviewed in family epidemiology, and are, for the most part, modest.

In the long term, genotyping patients for CD- and UC-associated genes will enable the determination of risk to relatives of IBD patients and of the optimal therapy for each individual. Identifying the genes that predispose to each pathogenetic mechanism of IBD will point research into new directions to develop therapies and will enable the construction of mouse models for the testing of those therapies before starting clinical trials. The use of this genetic information in the nearest term is perhaps suggested by several preliminary IBD pharmacogenetic studies.

Because glucocorticoids are known substrates for a drug efflux pump protein (P-glycoprotein 170) expressed by the *MDR* gene (SLC11A1, *MDR1*), the expression of this pump on the surface of lymphocytes was compared between IBD patients and controls, and increased *MDR* expression was observed in CD and UC patients who required surgery because they failed medical therapy (473). This observation suggests that a genetic variation that affects the pharmacology of steroids may lead to the ineffectiveness of these drugs in some IBD patients, and so the genetic contribution of SLC11A1 to IBD may be of interest to choosing proper therapies for individual patients.

Clinical response to 6-mercaptopurine (6-MP) depends on its conversion to 6-thioguanine (6-TG) and reaching a TG level  $>235$  (pmol/ $8 \times 10^{-8}$  erythrocytes) (474). Patients heterozygous for mutations that reduce the level of the enzyme thiopurine methyltransferase (TPMT) are able to attain this therapeutic level more readily on a given dose of 6-MP because the drug is not converted into inactive nucleotides by this enzyme (e.g. 6-methylmercaptopurine or 6-MMP). These results suggest that TPMT genotyping may assist the clinician in optimizing the therapeutic response to 6-MP and in identifying individuals at increased risk for drug-induced toxicity.

Patients in the original successful clinical trial of the anti-TNF antibody (385) were also typed for ANCA status and genotyped in the TNF region of MHC (396). The response of pANCA patients was the lowest and not significantly different from placebo, and the response of sANCA patients (a different type of staining from pANCA) was the highest in this study. Homozygotes for the LTA Ncol-TNFC-aa13L-aa26 haplotype “1-1-1-1” did not respond to treatment. Although these results must be interpreted with a great deal of caution because of the many comparisons made in this small study, these results raise the intriguing possibility that sANCA may identify a CD subgroup with a better response to Infliximab and that pANCA and homozygosity for the LTA “1-1-1-1” haplotype may identify CD subgroups with a poorer response (396).

These studies each raise the possibility that the use of specific genetic markers, involved in either metabolism of the therapeutic agent or in the susceptibility to a form of IBD, may well guide therapy in the not-too-distant future.

### 69.1 INTRODUCTION

Bilirubin, the major yellow pigment in plasma is the degradation product of heme, the iron-containing tetrapyrrole chromophore of hemoglobin and several important enzymes. Owing to its internal hydrogen bonding, bilirubin is very sparsely soluble in water and is toxic to neural and other tissues. It is rendered harmless by a series of physiologic processes, including binding to plasma proteins, rapid uptake by hepatocytes, conjugation with sugars to form polar derivatives, and efficient bile canalicular excretion. Perhaps because of its distinctive color, bilirubin has attracted the attention of physicians, chemists, and biologists since antiquity. Excessive accumulation of bilirubin in the serum is an indicator of liver dysfunction, and serum bilirubin analysis is used as a routine “liver function test.” Bilirubin throughput by the liver has also been studied as a model for hepatic disposal of other biologically important organic anions of limited aqueous solubility. Investigations into the molecular mechanisms of inherited disorders of bilirubin metabolism in humans and animals have provided important insights into bilirubin’s metabolic pathways. Newer aspects of bilirubin disposal and its relationship with biliary excretion of other substances are continuing to be unveiled by the efforts of numerous laboratories. Definitive treatment of some of these disorders remains a therapeutic challenge and continues to stimulate research. Although physicians have been mainly concerned with the toxic effect of bilirubin, the antioxidant property of the pigment may impart it a cytoprotective role.

This chapter provides a brief description of the chemistry, toxicity, and disposition of bilirubin, followed by a description of clinical situations in which various aspects of bilirubin throughput are disturbed.

### 69.2 FORMATION OF BILIRUBIN

Approximately 250–400 mg of bilirubin is produced daily in humans from heme catabolism. Normally, hemoglobin of senescent erythrocytes account for 80% of bilirubin production (1), and the remainder is derived from other heme-containing proteins and enzymes, and free heme. Intravenously administered radiolabeled heme precursors, glycine and  $\delta$ -aminolevulinic acid, are incorporated into bile pigments in two phases (1,2,4). The “early-labeled peak” of bilirubin (ELB) is excreted in bile during the first 3 days, and contains 20% of the radiolabel. The ELB consists of an initial “fast” component, comprising two-thirds of the peak in humans, and is largely derived from hepatic hemoproteins such as cytochromes, catalase, peroxidase, and tryptophan pyrrolase (4), and a rapidly turning over pool of free heme in the cytosol of hepatocytes (5), a fraction of which may be degraded without incorporation into heme proteins (6). Induction of hepatic cytochrome P-450 enhances the ELB (7). As  $\delta$ -aminolevulinic acid is preferentially incorporated into hepatic hemoproteins, when labeled  $\delta$ -aminolevulinic acid is used as a precursor, only the initial component of the ELB incorporates radioactivity (4). This is followed by the relatively “slower” phase of the ELB, which normally contains one-third of the peak and

is derived from erythroid and nonerythroid sources. This phase is enhanced during “ineffective erythropoiesis,” as in congenital dyserythropoietic anemias, megaloblastic anemias, iron-deficiency anemia, and lead toxicity and erythropoietic porphyria (9). The slower component of the ELB is also enhanced during accelerated erythropoiesis from any cause because of intramedullary destruction of some normoblasts, destruction of reticulocytes in the peripheral circulation (10), and trimming of segments of reticulocytes during maturation (11). Normally, 80% of the radiolabel is excreted as the “late-labeled peak,” which is derived from the hemoglobin of senescent erythrocytes and appears approximately 50 days and 100 days after intravenous injection of the precursors in rats and humans, respectively (4). In hemolytic syndromes or acute intravascular or extravascular hemolysis, the life span of erythrocytes is shortened and the late-labeled peak appears earlier.

### 69.2.1 Enzyme-Mediated Opening of the Heme Ring

Heme (ferroprotoporphyrin IX) consists of four pyrrole rings connected by methane bridges and a single iron in the center (Figure 69-1). The ring is opened by oxidation of the  $\alpha$ -methene-bridge carbon, catalyzed by heme oxygenase, a group of enzymes located in the endoplasmic reticulum. This reaction requires NADPH and oxygen, and results in the elimination of the  $\alpha$ -methene-bridge carbon as CO (12); release of iron, which is reutilized; and formation of biliverdin, a green pigment (Figure 69-1). High levels of heme oxygenase activity are found in organs involved in hemoprotein breakdown, such as the spleen, where senescent erythrocytes are sequestered. In the liver, both hepatocytes and Kupffer cells have heme

oxygenase activity; the activity in the Kupffer cells is as high as in the spleen (13). Three forms of heme oxygenase have been identified (14). Heme oxygenase 1 (HO-1), a 32-kDa protein, is a stress-response protein. It is induced by stress-related agents, such as endotoxins (e.g. lipopolysaccharide), several cytokines, heavy metals, hypoxia, and reactive oxygen species. HO-1 is also induced by protoheme IX, oxidized and low-density lipoprotein, and probably also by the shear stress on endothelial cells in the cirrhotic liver (15–17). Nuclear factor- $\kappa$ B and p38 mitogen-activated protein kinase signaling pathways mediate the lipopolysaccharide-dependent induction of HO-1 via the proximal promoter region of the gene. The lipid peroxidation end product 4-hydroxy-nonenal (HNE) and phospholipids are natural components of oxidized LDL and mediate the stabilization and nuclear translocation of the anti-inflammatory nuclear factor E2-related factor 2 (Nrf2), thereby enhancing the transcription of HO-1 (18). By converting the pro-oxidant heme to antioxidant biliverdin and bilirubin, it serves as a cellular defense mechanism against oxidative injury. HO-1 expression in response to inflammatory mediators may contribute to resolving inflammatory responses, thereby protecting several organs against oxidative injury. Both CO and biliverdin/bilirubin, which are the products of HO-1, have been implicated in this response. In the gastrointestinal tract, HO-1 induction is associated with protection against injury caused by ischemia-reperfusion, indomethacin, lipopolysaccharide-associated sepsis, trinitrobenzene sulfonic acid, and dextran sulfate sodium (19). In the presence of hypercholesterolemia, HO-1-deficient mice develop early atherosclerosis. In humans, HO-1 deficiency is associated with growth retardation, hyperlipidemia, and endothelial damage, which may cause consumption coagulopathy and microangiopathic hemolytic anemia. Inducible HO-1 is an important cytoprotectant in the renal vascular endothelium and tubular epithelium. It is likely that HO-1 has additional effects that may not be mediated by CO or bilirubin. For example, human mesenchymal stem cells induce subsets of regulatory T-lymphocytes in an HO-1-dependent manner (20). In certain conditions, induction of HO-1 may result in increased iron deposition in tissues, with deleterious effects. In Alzheimer’s disease, HO-1 induction in astroglial cells by  $\beta$ -amyloid and hydrogen peroxide is thought to cause mitochondrial nontransferin iron sequestration, thereby contributing to bioenergy failure (21). Finally, the cytoprotective effect of HO-1 may have a deleterious effect as seen in the case of prostate cancer progression (22).

Heme oxygenase 2 is a constitutive protein, expressed primarily in the brain and the testis. The catalytic activity of heme oxygenase 3 is very low; this isoform may function mainly as a heme-binding protein. CO released by heme-oxygenase-mediated oxidation of the  $\alpha$ -carbon bridge is a potent vasodilator that regulates the vascular tone in the liver and in other organs, such as the heart, under conditions of stress.

**FIGURE 69-1** Mechanism of heme ring opening and subsequent reduction of biliverdin to bilirubin. Oxidation of the  $\alpha$ -carbon bridge catalyzed by microsomal heme oxygenase results in the elimination of the carbon as CO, resulting in opening of the heme ring.

**69.2.1.1 Heme Oxygenase Inhibitors.** Non iron metalloprotoporphyrins, such as tin- and zinc protoporphyrin, bind to heme oxygenase with greater affinity than heme (23), but are not degraded. These dead-end inhibitors of heme degradation (23,24) strongly suppress heme oxygenase activity, thereby suppressing bilirubin formation.

## 69.2.2 Reduction of Biliverdin to Bilirubin

In most mammals, biliverdin is converted to the orange pigment bilirubin by the action of biliverdin reductase, which utilizes NADH at pH 6.7 and NADPH at pH 8.5 as cofactors (25). Variants of cytosolic biliverdin reductase, isolated from rat liver and spleen (27), are post-translational derivatives of a single-gene product (25,28).

Because bilirubin is almost quantitatively excreted in bile, bilirubin production can be measured by determination of biliary excretion in experimental animals. In humans, it can be estimated by quantifying fecal and urinary urobilinogen and stercobilinogen, the bacterial degradation products of bilirubin (29). The rate of bilirubin formation can also be determined from the turnover of intravenously administered radioisotope-labeled bilirubin (30). More conveniently, bilirubin formation can be estimated by measuring CO production using a closed rebreathing system. Oxidation of the  $\alpha$ -carbon bridge of heme is the main source of endogenous CO production although a small fraction may be contributed by other sources. Therefore, CO production can be calculated from the CO concentration in the breathing chamber or from an increment in blood carboxyhemoglobin saturation (31).

## 69.3 STRUCTURE OF BILIRUBIN

The planar chemical structure of bilirubin (Figure 69-2) was determined by Fischer and Plieninger (32). Despite the presence of two propionic acid side chains and four amino groups, bilirubin IX $\alpha$  is nearly insoluble in water at physiologic pH. An explanation for this phenomenon was suggested by Fog and Jellum (34) and by Kuenzle et al. (35), who proposed that bilirubin IX $\alpha$  may be internally stabilized by hydrogen bonding between the propionic acid carboxyls and the two external pyrrolenone rings. Such intramolecular hydrogen bonding has been confirmed by X-ray diffraction studies (i). These hydrogen bonds constrain the molecule into a "ridge tile" conformation and engage all polar groups of the molecule, rendering it insoluble in water (Figure 69-2). For steric reasons, the hydrogen-bonded structure requires that the interpyrrolic bridges at the 4 and 15 positions of bilirubin should be in a trans- or Z configuration (37). Addition of methanol, ethanol or 6-M urea interferes with hydrogen-bonded structure and makes bilirubin more labile, water soluble, and rapidly reactive with diazo reagents. Conjugation of the propionic acid carboxyls

with sugar moieties disrupts the hydrogen bonds, resulting in the formation of water-soluble metabolites that are readily excreted in bile.

## 69.3.1 Absorption Spectra

Bilirubin IX $\alpha$  has a main absorption band at 450–474 nm in most organic solvents and an extinction coefficient of 48.0–63.4/mmole at its absorption maximum at 1-cm path length.

## 69.3.2 Photoisomerization of Bilirubin

Exposure of circulating bilirubin to light changes the configuration of one or both of the interpyrrolic bridges at the 5 and 15 positions to E or cis-configuration, which sterically hinders hydrogen bonding. The resulting 4Z-15E or 4E-15Z isomers lack hydrogen bonds in one half of the molecule, whereas bilirubin IX $\alpha$ -EE lacks hydrogen

**FIGURE 69-2 Upper Panel.** Hydrogen-bonded structure of bilirubin. The bilirubin molecule is contorted into a ridge-tile-like configuration caused by internal hydrogen bonding (interrupted line) of the propionic acid carboxyls to the amino groups and the lactam oxygen of the pyrrolenone rings of the opposite half of the molecule. The carbon bridges connecting pyrrolenone rings A and B (C-4) and C and D (C-15) are in the Z (trans-) configuration. By engaging the polar groups (propionic acid carboxyls and the amino and lactam groups), hydrogen bonding renders the bilirubin molecule very sparsely soluble in water. Because the central carbon bridge (C-10) is buried deep within the molecule, conjugated bilirubin reacts very slowly with diazo reagents, unless the hydrogen bonds are disrupted by adding "accelerator" reagents ("indirect diazo reaction"). **Lower Panel.** Glucuronidation of both propionic acid carboxyls results in the formation of bilirubin diglucuronide, the predominant pigment excreted in normal human bile. Glucuronidation disrupts the internal hydrogen bonds, making the molecule water soluble and exposing the central carbon bridge (C-10) to diazo reagents, resulting in "direct diazo reaction."

bonds on both halves of the molecule. Blue light is more efficient in mediating the conformational changes. Following absorption of two photons (38), the vinyl substituent at position C3 of bilirubin IX $\alpha$ -4E-15Z is cyclized with the methyl substituent on the internal pyrrole ring, forming the structural isomer E-cyclobilirubin or lumirubin (39,40). Although the rate of cyclization is slower than that of the formation of configurational isomers, because of the greater stability of lumirubin, this form may be quantitatively more important in phototherapy of neonatal jaundice (39). The photoisomers are more polar than is bilirubin IX $\alpha$ -ZZ and can be excreted in bile without conjugation (42).

## 69.4 POSSIBLE PHYSIOLOGIC BENEFITS OF BILIVERDIN AND BILIRUBIN

Generation of biliverdin and bilirubin, and the subsequent glucuronidation and canalicular transport of bilirubin, are all energetically expensive mechanisms. The evolutionary conservation of these pathways suggests a physiologic benefit of bilirubin. The antioxidant effect of bilirubin may be important during the neonatal period, when the body concentration of other natural antioxidants is low. In adults, a weak but statistically significant inverse relationship between serum bilirubin levels and the risk of coronary artery disease has been reported (43). Analysis of the Third National Health and Nutrition Examination Survey (NHANES III) database revealed that, in over 176 million individuals in the United States, the odds ratios of a history of colorectal cancer were reduced to 0.295 in men and 0.186 in women per 1-mg/dL increment of serum bilirubin levels (44). Similarly, an inverse relationship between serum bilirubin levels and cancer mortality was seen in a large study in Belgian population (45). These impressive statistical data, however, do not establish conclusively a cause-and-effect relationship, because of the possible existence of confounding variables.

## 69.5 TOXIC EFFECTS OF BILIRUBIN

The toxic effect of bilirubin on the neonatal brain has been known for many centuries. Bilirubin deposition at specific areas of the brain accompanied by structural damage is termed *kernicterus*. At elevated concentrations, unconjugated bilirubin, particularly its non-albumin-bound fraction, is toxic to astrocytes and neurons. Mitochondrial damage results in impaired energy metabolism and apoptosis, while injury to plasma membranes may disrupt the transport of neurotransmitters (46). The study of mutant Gunn rats that lack hepatic bilirubin glucuronidating activity (see later) has been pivotal in the understanding of the neurotoxicity of bilirubin. This is the only naturally mutant animal model, in which bilirubin-induced brain damage has been known to occur. Structural and functional damages of the cochlear nuclei, resulting in hearing deficiency, are

a common complication of several hyperbilirubinemia in human neonates. Cells of the auditory system that receive synaptic input from end-bulbs or calyces appear to be early targets (47). In Gunn rat pups, these morphologic changes correlate with brainstem auditory evoked potentials (48). Tight binding of unconjugated bilirubin to plasma albumin inhibits deposition of bilirubin in the brain. Displacement of bilirubin from albumin binding enhances the net transfer of bilirubin into neural tissues (50). Administration of sulfonamides in Gunn rats results in reversible brainstem auditory evoked potential abnormalities (51).

Purkinje cells of the cerebellum, hippocampus, and basal ganglia are also common targets of bilirubin deposition in Gunn rats and human infants with overt kernicterus. Purkinje cells of the cerebellum are affected in Gunn rats at the age of 7 days. Subsequent degeneration of these cells results in cerebellar hypoplasia (52). Purkinje cells that recover and persist into adult life may have abnormalities of synapse formation with other Purkinje cells or with neural cells of other types. There is enlargement and distortion of cerebellar mitochondria (54) and increased activities of the lysosomal enzymes in Gunn rats by the eighth day of life (55). Cerebellar cyclic GMP concentrations decrease progressively from day 15 to day 30, but cyclic AMP (cAMP) levels remain normal (56). Inhibition of cytochrome c oxidase activity and ascorbate-driven oxygen consumption in neonatal rat cortical neuronal cells by unconjugated bilirubin may lead to neuronal apoptosis (57).

### 69.5.1 Clinical Features of Bilirubin Neurotoxicity

In most cases, kernicterus occurs during the first few months of life. In patients with inherited absence of bilirubin glucuronidation, who may survive through infancy, kernicterus may occur during adolescence or early adulthood. Overt kernicterus usually presents between the third and sixth day of life with loss of the Moro reflex, hypotonia, athetoid movements, and reflex opisthotonus in response to startling stimuli. Left untreated, this progresses to atonia and death. In some cases, bilirubin encephalopathy may present late, with cerebellar symptoms as the presenting feature (58). Chronic effects of bilirubin encephalopathy may be observed in patients who survive acute kernicterus. These include chronic hearing abnormalities, athetoid movements, paralysis of upward gaze, and mental retardation.

Autopsy of infants dying during the acute phase of kernicterus shows bilirubin staining of the hippocampus, basal ganglia, and nuclei of the cerebellum and the brainstem (59). However, yellow staining is not found in children dying in the chronic stage of bilirubin encephalopathy. In these cases, focal necrosis of neurons and glia are observed. Gliosis of the affected area is seen in chronic cases (60).

Because histologic lesions are not present from the onset of clinical kernicterus (60), these may not be the initiating pathophysiologic events. Focal bilirubin staining of the brain may also occur in other forms of brain injury, such as cerebral hemorrhage (61), and does not, by itself, establish the diagnosis of kernicterus.

Serum unconjugated bilirubin levels above 20.0 mg/dL are usually considered dangerous (62). However, in some studies, serum bilirubin levels that are not high enough to cause kernicterus have been reported to result in an increased incidence of neurologic abnormalities or decreased intellectual performance later in life (63,64).

### 69.5.2 Pathophysiology of Kernicterus

Immaturity of the blood–brain barrier in neonates has been implicated in the high incidence of kernicterus in neonates. Tight junctions between capillary endothelial cells and foot processes of astroglial cells provide a structural barrier to equilibration of hydrophilic water-soluble substances and proteins in blood with those in the brain (65). The functional counterpart of this barrier consists of specific transport mechanisms that are involved in the translocation of ions, water, and nutrients from plasma to brain. Despite a long-standing interest in the blood–brain barrier in the newborn, it has been difficult to confirm an enhanced passage of labeled markers (66) into the immature brain, and the evidence for an immature blood–brain barrier in the neonate is not convincing.

Infusion of hypertonic urea (68) or arabinose in the carotid artery of newborn rats results in osmotic shrinkage of capillary endothelial cells, thereby opening the blood–brain barrier transiently. While the barrier remains open, intravenously administered albumin-bound bilirubin rapidly enters the brain. After discontinuation of the hyperosmolar infusion, the blood–brain barrier becomes reconstituted, and bilirubin is rapidly cleared from the brain (69). Accumulation of unconjugated bilirubin in the cerebrospinal fluid and the brain tissue is limited by its active export, probably mediated by multidrug-resistance-related protein-1 (MRP1/ABCB1), the ATP-dependent pump, present in choroid plexus epithelia, capillary endothelia, astrocytes, and neurons (46). Unconjugated bilirubin may downregulate MRP1/ABCB1 in cells constituting the blood–cerebrospinal fluid barrier, thereby potentiating bilirubin encephalopathy (70). Clearance of bilirubin may be inefficient in damaged and edematous brains, which may bind bilirubin (71). Therefore, bilirubin may be more toxic to brains that are already damaged from other causes.

### 69.5.3 Biochemical Mechanism of Bilirubin Toxicity

Bilirubin inhibits a vast array of metabolic, enzymatic, and synthetic functions of the brain. However, it is not

clear whether these toxic effects, observed in tissue culture or in vitro, are relevant in the clinical manifestation of bilirubin encephalopathy. Bilirubin may uncouple oxidative phosphorylation and inhibit ATPase activity of brain mitochondria (73). Bilirubin reduces local cerebral glucose utilization in immature rats, particularly in the auditory, visual, hypothalamic, and thalamic regions (74). Bilirubin inhibits non-cAMP-dependent protein kinase activity in vivo (75). Irreversible inhibition of  $\text{Ca}^{2+}$ -activated, phospholipid-dependent protein kinase C activity and cAMP-dependent protein kinase activity has been reported (76,77), suggesting that an abnormality of protein phosphorylation may play a role in bilirubin encephalopathy in the newborn.

### 69.5.4 Bilirubin Nephrotoxicity

In Gunn rats (78) and hyperbilirubinemic infants (79), deposition of unconjugated bilirubin in the renal medulla results in medullary necrosis and formation of visible bilirubin crystals on the papillae. Impairment of urinary concentration resulting from an abnormality of the ascending loop of Henle occurs in Gunn rats (78,80), but not in mature neonates with hyperbilirubinemia (81) or adult patients with Crigler–Najjar syndrome type I (82).

## 69.6 DISPOSITION OF BILIRUBIN

Similar to many other water-insoluble substances, bilirubin remains tightly bound to plasma proteins, particularly albumin. In the liver, the albumin–bilirubin complex dissociates and bilirubin, but not albumin, is internalized. Within the cytosol, bilirubin is stored bound to cytosolic proteins, particularly to glutathione-S-transferases (GSTs). Bilirubin is rendered water soluble by conjugation with glucuronic acid, catalyzed by a microsomal bilirubin uridine diphosphoglucuronate glucuronosyltransferase (UGT1A1). Bilirubin glucuronides are transported across the bile canalicular membrane and are carried to the duodenum by the bile duct. Other substances that are sparingly water soluble, or are organic anions in nature, and are destined to be excreted in the bile, share some of these steps with bilirubin. The steps of bilirubin throughput are briefly described in this section and are schematically shown in Figure 69-3.

### 69.6.1 The Role of Albumin

Owing to its structural peculiarity (see earlier), bilirubin is only sparingly water soluble at physiologic pH. Binding to albumin keeps the pigment in solution and prevents its deposition into tissues, including the brain. Thus, albumin facilitates the transport of bilirubin to the liver and prevents its toxic effects. Although inherited analbuminemia is compatible with life, the biliary recovery of amphipathic compounds such as bilirubin

**FIGURE 69-3** A schematic diagram summarizing the metabolism of bilirubin by hepatocytes. In plasma, bilirubin is tightly but reversibly bound to albumin. In liver sinusoids, the albumin–bilirubin complex comes in direct contact with the basolateral domain of the hepatocyte plasma membrane (sinusoidal membrane) through fenestrae of the specialized hepatic endothelial cells, where the albumin–bilirubin complex dissociates. Bilirubin is taken up by the facilitated diffusion, the molecular basis of which is not fully understood. Within the hepatocyte, bilirubin is stored bound to glutathione-S-transferases (GSTs), which inhibit its efflux from the cell, thereby increasing the net uptake. Glucuronidation of bilirubin in the endoplasmic reticulum is catalyzed by uridine diphosphoglucuronate glucuronosyl-transferase-1 (UGT1A1), forming bilirubin monoglucuronide and diglucuronide. Conjugated bilirubin is secreted across the bile canaliculus by an energy-requiring transporter, MRP2, and to a lesser extent by electrogenic transport. Canalicular transport of bilirubin is shared by other many organic anions, including glucuronides and glutathione conjugates, but not by most bile salts.

and bromosulphophthalein (BSP) is reduced in genetically analbuminemic rats (83). In this situation, other plasma proteins take over some of the functions of albumin. The neural toxic effect of bilirubin is markedly enhanced in the analbuminemic rat.

There are a primary and a secondary binding site on albumin for bilirubin (84), and some weaker binding sites may exist (86,87). The lysine 240 in human albumin and lysine 238 in bovine serum albumin appear to be primary bilirubin-binding sites (88). Other ligands that bind at the same site as bilirubin, such as sulfonamides, anti-inflammatory drugs, and cholecystographic contrast media, may displace bilirubin competitively from albumin (86), thereby precipitating bilirubin encephalopathy in newborns (89), without changing serum bilirubin levels.

Normally, albumin is present in molar excess to bilirubin. The reserve bilirubin-binding capacity of albumin acts as a buffer for rapid fluctuations of serum bilirubin levels as in acute hemolysis. Owing to the influence of many metabolites and drugs on albumin binding of bilirubin, measurement of unbound plasma bilirubin and the reserve bilirubin-binding capacity provides a more accurate estimate of the risk of brain damage from unconjugated bilirubin than does the measurement of total bilirubin concentrations alone. Unbound bilirubin in serum can be quantified by the gel chromatography

(90), peroxidase treatment (52), electrophoretic analysis (91), and fluorometry (92). In conditions associated with the presence of conjugated bilirubin in plasma for a long duration, bilirubin becomes irreversibly bound to albumin (93). Owing to the long half-life of albumin, this fraction, which is not cleared by the liver or kidney, lingers for a long time in serum.

### 69.6.2 Bilirubin Uptake by Hepatocytes

Bilirubin is delivered to the liver bound to plasma albumin. Because the endothelial lining of hepatic sinusoids is fenestrated, the albumin–bilirubin complex comes in direct contact with the sinusoidal and basolateral plasma membrane domains of the hepatocyte. Bilirubin dissociates from albumin at or close to the hepatocyte surface before it is taken up into the hepatocyte. Whether this dissociation is facilitated by an albumin receptor at the hepatocyte surface remains speculative. In the presence of spontaneous portosystemic shunts, as in cirrhosis of the liver, or surgically induced diversion of portal blood from the liver, bilirubin produced in the spleen does not come in contact with hepatocytes in the first pass. This results in a mild unconjugated hyperbilirubinemia. An open ductus venosus in the newborn may exacerbate “physiologic” jaundice in infants by a similar mechanism.

Bilirubin is taken up by the hepatocyte by facilitated diffusion (94), which is bidirectional and does not consume energy, but needs the presence of inorganic anions, such as  $\text{Cl}^-$  (95,96). The mechanism of bilirubin uptake at the sinusoidal surface is not yet understood precisely (97,98). Unconjugated bilirubin is relatively nonpolar, and some investigators have suggested that it may diffuse through the sinusoidal membrane simply by dissociating from albumin, without requiring transporter proteins (99). However, concentrative bilirubin uptake is a hepatocyte-specific function (100). Therefore, hepatocyte-specific carrier proteins have been sought. OATP2 (also known as OATP-C or SLC21A6) in human liver and OATP4 (S1c21a10) in rat liver are high-affinity transporters of organic anions such as BSP, taurocholate, estradiol-17 $\beta$  glucuronide, LTC4, estrone-3-sulfate and estrone-1-sulfate, dehydroepiandrosterone sulfate, triiodothyronine, and thyroxine (101,102). Some studies have suggested that OATP-C also transports unconjugated bilirubin (101), but other studies did not support this conclusion (103). NTCP (SLC10A1) is a specialized carrier for the  $\text{Na}^+$ -dependent hepatic uptake of bile salts (104–107), which does not appear to be directly related to bilirubin uptake. Thus, the physiologically important bilirubin transporter remains to be identified at this time.

### 69.6.3 Storage of Bilirubin within the Hepatocyte

Within the hepatocyte, bilirubin binds to cytosolic proteins that keep it in solution predominantly. The

bilirubin-binding proteins were originally termed the Y (ligandins) and Z (fatty-acid-binding) proteins (108). Later, the Y proteins or ligandins were found to consist of the  $\alpha$  class of GSTs (109). Binding to GSTs does not affect the influx of bilirubin directly, but increases the net input by inhibiting its diffusion out of the hepatocytes (110).

### 69.6.4 Bilirubin Conjugation

**69.6.4.1 Conversion of Bilirubin to Polar Derivatives.** Conjugation of the propionic acid carboxyls with sugar moieties, particularly glucuronic acid (111), is the major mechanism by which the internal hydrogen bonds of bilirubin are disrupted and the molecule becomes water soluble. Depending on whether one or both propionic acid carboxyls are glucuronidated, bilirubin monoglucuronide or diglucuronide is formed (113), both of which are efficiently excreted in bile. Bilirubin diglucuronide is the major pigment in normal human and dog bile (111). In addition, smaller amounts of glucosyl and xylosyl conjugates have been described in human T-tube bile (113,115) and bile from other species (116).

**69.6.4.2 Enzyme-Catalyzed Glucuronidation of Bilirubin.** A family of enzymes termed uridine diphosphoglucuronate glucuronosyltransferases (UGTs; EC 2.4.1.17), located in the endoplasmic reticulum and nuclear envelope of a variety of cells (117), catalyzes the transfer of the glucuronosyl moiety of UDPglucuronate to aglycone substrates. Substrates of this group of enzymes comprise a wide spectrum of substances, including hormones (e.g. steroid hormones, thyroid hormones, and catecholamines), endogenous metabolites (e.g. bile salts and bilirubin), numerous drugs and their intermediate metabolites, toxins (e.g. carcinogens), and laboratory xenobiotics (118). The products of the transferase reaction are ether, ester, thiol, and N-glucuronides. Glucuronides are more polar than the aglycone substrates and usually less biologically active. Because of the wide array of substrates that are conjugated via UGTs, this group of enzymes constitutes a major detoxification system of the body.

The catalytic activity of UGTs is partly latent in microsomal vesicles. Full enzyme activity is obtained by perturbing the microsomal membrane by detergent (119) or enzymatic (120) treatment. UDP-N-acetylglucosamine, which activates hepatic microsomal UGT activity at low concentrations, may be a physiologic activator of the UGTs. According to one postulated model, the catalytic site of UGT is located inside the lumen of the endoplasmic reticulum, and the donor substrate, UDP-glucuronic acid, must be transported through the membrane barrier to the catalytic site (121). In this model, UDP-N-acetylglucosamine is thought to increase UDP-glucuronate transport by activating a putative “permease.” Detergents and other membrane-perturbing agents

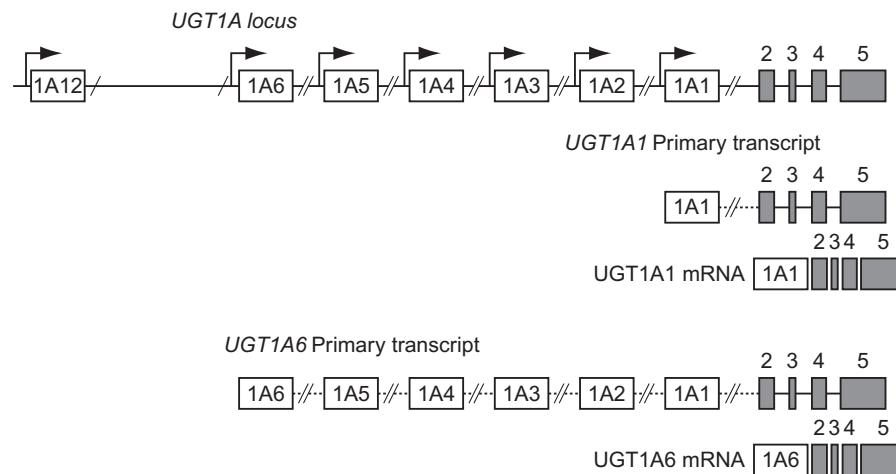

may enhance UGT activity in vitro by physically increasing the permeability of the membranes to UDP-glucuronic acid (122). An alternative model proposes that the physical or chemical activators of UGT act by releasing the membrane constraint of UGT (123), and UDP-N-acetylglucosamine acts as an allosteric activator of the enzyme. It should be noted that the two models may not be exclusive of each other.

The carboxy-terminal domain of all UGT isoforms has a high level of sequence homology, and is thought to bind the common substrate, UDPglucuronic acid (124). The amino-terminal domain is less homologous in structure and imparts aglycone substrate specificity to the enzymes (125).

**69.6.4.3 Families and Subfamilies of UGT.** The UGT system consists of a large number of structurally related enzymes, all of which accept UDPglucuronic acid as a donor substrate, but differ in aglycone substrate specificity (126–128,130,131). UGT isoforms differ in ontogenic development (132) and effect of enzyme inducing agents (133). On the basis of the extent of structural homology of the respective messenger RNAs (mRNAs), UGT isoforms have been classified into several families and subfamilies (134). The UGT1A locus expresses one group of UGT isoforms (135). The enzymes have identical carboxy-terminal domains (136–138), but variable amino-terminal regions. The UGT1A locus consists of four consecutive exons (exons 2–5) at the 3' end, which are used in the mRNAs of all isoforms expressed from this locus and encode the identical carboxy-terminal domain (Figure 69-4). Upstream to these are a series of 13 unique exons, each preceded by a promoter. Only one of these exons is used in a given UGT isoform. The process of transcription can start at any of the promoters, giving rise to transcripts of different lengths. The presence of a separate promoter upstream to each of these variable-region exons explains independent regulation of enzymes expressed from this gene and their different organ distribution and expression during ontogeny, enzyme induction, or carcinogenesis. Enzyme activity toward 4-nitrophenol and other simple phenolic substrates develops in late fetal life in rats, whereas activity toward bilirubin develops after birth (132). UGT1A6, a 3-methylcholanthrene-inducible isoform, is permanently overexpressed in carcinogen-induced preneoplastic nodules in rat liver (137). Triiodothyronine treatment results in a threefold increase in rat liver phenol-UGT activity, whereas bilirubin glucuronidation is reduced by 80% (139).

The unique exon that is located at the 5' end of the transcript is spliced to exon 2, and the intervening sequences are spliced out. In this manner, the UGT1A locus expresses nine UGT isoforms (the other four unique exons represent pseudogenes). Thus, the UGT1A locus is considered to comprise multiple overlapping genes, each of which is named according to the unique exon that is used in the processed mRNA. For example,

**FIGURE 69-4** A schematic representation of the human UGT1A locus. This locus is located in chromosome 2 at 2q37 (373). Exons 2–5 are shared by all UGT isoforms expressed from this locus. Upstream to these common-region exons, there is a series of variable-region exons, designated exons UGT1A1 through UGT1A12, only one of which is used in any given UGT isoform. Each of these exons encodes the variable amino-terminal region of one UGT isoform. Each variable-region exon has an upstream promoter element, and is differentially regulated. Depending on the promoter selection, primary transcripts of various lengths are produced. The variable exon 1 at the 5' end of the transcript is spliced to the common exons 2–5, resulting in the formation of a mature messenger RNA (mRNA) with a unique exon 1. Several species of UGT mRNAs are produced in this manner, all of which have identical 3' domains. Therefore, a genetic lesion in any of the common-region exons affects all mRNAs expressed from this locus.

if transcription starts at the 3'-most unique exon, the gene is termed *UGT1A1*. On the other hand, if the transcription starts at the sixth unique exon, the gene is termed *UGT1A6*. Initially, *UGT1A1* and *UGT1A4* were reported to have activity toward bilirubin in humans (140), but later, only *UGT1A1* was shown to contribute physiologically significant bilirubin glucuronidating activity (53). The *UGT1* gene in the rat has a similar exon organization (136), indicating that this gene is highly conserved during evolution.

### 69.6.5 Excretion of Conjugated Bilirubin across the Bile Canalculus

In contrast to the transport across the sinusoidal surface plasma membranes, canalicular secretion of conjugated bilirubin and other cholephilic compounds occurs against a high concentration gradient, whereby the liver:bile concentration ratio for organic anions, such as dibromosulfophthalein, may reach 1:1000 (143). Such large gradient cannot be accounted for by the  $-35$  mV potential difference across the canalicular membrane, and suggest the presence of active transport systems (144–147). MRP2 (also termed ABCC2), a member of the ATP-binding cassette (ABC) protein family, serves as the canalicular efflux pump for non-bile-acid organic anions, including bilirubin and other glucuronide and glutathione conjugates (148–150). Genetic deficiency of MRP2/ABCC2 in humans leads to the Dubin–Johnson syndrome, characterized by retention of conjugated bilirubin in plasma (152,153). The TR– rat, which lacks mrp2/ABCC2 function because of a single-nucleotide deletion of the *mrp2/abcc2* gene, is an animal model of Dubin–Johnson syndrome (154,155). Sequence analysis

of the human MRP2/ABCC2 promoter showed a number of putative consensus binding sites for both ubiquitous and liver-enriched transcription factors, including AP1, SP1, HNF1, and HNF3 $\beta$  (156,157), as well as the nuclear receptors CAR, PXR, and FXR.

Two other ABC family proteins, mrp1 and mrp3, are expressed at low levels in rat liver, but are upregulated during cholestasis (159,160). Both mrp1 and mrp3 are located in the basolateral membrane of the hepatocytes and pump accumulating bilirubin glucuronides out of the hepatocytes into the plasma (156,161). Mrp1 also pumps glutathione S-conjugates (162), as well as unconjugated bilirubin. Mrp3 expression is upregulated in the liver of mrp2-deficient rats and in UGT1A1-deficient Gunn rats (156). Thus, MRP3 (mrp3 in rodents) functions as a reverse transporter, which pumps substrates back to the blood when biliary excretion of glucuronides is reduced.

Several other ATP-dependent canalicular transporters have been identified and cloned. *FIC1* is a gene mapped to chromosome 18q21 (163), the product of which may couple the hydrolysis of ATP to the translocation of acidic phospholipids (e.g. phosphatidylserine and phosphatidylethanolamine) from the outer to the inner layer of the plasma membrane. The gene for another transport protein termed *bile salt export pump*, also known as sister of P-glycoprotein, is located on chromosome 2q24 (165). MDR3/ABCB4 in humans (*mdr2* in mice) mediates ATP-dependent translocation of phosphatidylcholine from the inner to the outer leaflet of the bile canalicular plasma membrane (166). Inherited defects of any of these genes result in disordered bilirubin excretion by direct or indirect mechanisms.

### 69.6.6 Nuclear Receptors

Nuclear receptors may orchestrate the various steps involved in bilirubin throughput: maximum capacities for bilirubin uptake, storage, conjugation, and canalicular excretion appear to be similar *in vivo*. Therefore, reduction of any of these steps can lead to hyperbilirubinemia. On the other hand, enhancement of bilirubin excretion, which may be needed when bilirubin production is increased, would require coordinated increase in the capacity of each. It has been proposed that the nuclear receptor, CAR, serves as the co-ordinating mechanism for physiologic modulation of each of these steps (167,168).

### 69.6.7 Degradation of Bilirubin in the Gastrointestinal Tract

The small amount of unconjugated bilirubin that reaches the intestine is partly reabsorbed. This reabsorption may be greater when the infant is fed maternal milk than when a baby formula is used. Therefore, breast-feeding may contribute to neonatal hyperbilirubinemia (169). Conjugated bilirubin is not substantially absorbed from the intestine (170). Intestinal bacteria deconjugate bilirubin (171) and degrade it to urobilinogens and related products (172). Urobilinogens absorbed from the intestine are re-excreted in the bile and, to a smaller extent, in the urine. In liver disease and increased bilirubin production, urinary urobilinogen excretion is increased. However, because the extent of reabsorption of urobilinogen by renal tubules varies, and the pigment is unstable in acid urine, quantification of urobilinogen excretion in urine is not of clinical benefit. However, complete absence of urobilinogen in stool and urine indicates complete bile duct obstruction. Urobilinogen is colorless. Its yellow oxidation product, urobilin, contributes to the characteristic color of urine and stool.

### 69.6.8 Extrahepatic Disposition of Bilirubin

During biliary obstruction, urinary excretion becomes the major excretory pathway for bilirubin (173). In children with biliary atresia, 50–90% of bilirubin excretion may occur through the kidney (174). Unconjugated bilirubin is tightly bound to albumin and is not filtered by normal renal glomeruli, and therefore does not appear in the urine. A fraction of conjugated bilirubin that is not bound to albumin is filtered by renal glomeruli (173) and is excreted in urine. Therefore, excretion of bilirubin in the urine, in the absence of albuminuria, indicates the presence of conjugated bilirubin in plasma. Unconjugated bilirubin entering the renal tubules is reabsorbed, but is not secreted by the tubules (175). Although UGT1A1 activity is present in the proximal small intestinal villi (117), the relative contribution of small intestine in bilirubin disposition is not known. Small amounts

of unconjugated bilirubin pass to the intestinal lumen across the intestinal epithelium or by exfoliation of the epithelial cells (176).

### 69.6.9 Alternative Pathways of Bilirubin Disposition

As discussed in the preceding sections of this chapter, exposure to light results in the formation of configurational (EZ, ZE, or EE forms) and cyclic (e.g. lumirubin) isomers of bilirubin formed in the presence of ambient light or during phototherapy. These isomers are more polar than bilirubin IX $\alpha$ -ZZ, and are excreted in bile in the unconjugated form (42). A significant fraction of bilirubin undergoes photodegradation to polar diazo-negative compounds that are excreted in bile and urine (38).

## 69.7 BILIRUBIN MEASUREMENT

Total serum bilirubin level and the conjugated bilirubin fraction are routinely determined as markers of liver function. In the newborn period, the fractional concentration of non-protein-bound bilirubin is a more reliable predictor of potential neurotoxicity, and helps in determining the need for institution of therapy to reduce serum bilirubin levels. Under some circumstances, the measurement of, covalently, albumin-bound bilirubin may add clinical insight to bilirubin disposition.

Serum bilirubin is usually measured after conversion to stable azo-derivatives, analysis of intact tetrapyrroles being mainly used for research on bilirubin metabolism (177).

### 69.7.1 Bilirubin Measurement Following Reaction with Diazo Reagents

Reaction with a diazonium ion cleaves the bilirubin molecule at the central carbon bridge, and derivatizes the two resulting dipyrroles at the C9 and C11 positions of bilirubin (178). Because conjugated bilirubin lacks internal hydrogen bonds, the central methane bridge is readily accessible to the diazo reagents. Therefore, conjugated bilirubin reacts rapidly with diazo reagents (“direct” fraction) (179). On addition of “accelerator” substances, such as methanol or caffeine, both conjugated and unconjugated bilirubin react rapidly (total bilirubin). The “indirect” fraction of bilirubin is calculated by subtracting the “direct” fraction from total bilirubin. In order to characterize the azodipyrroles, they can be separated by thin-layer chromatography (180) or high-performance liquid chromatography (HPLC) (181). Because up to 15% of unconjugated bilirubin in solution may exhibit direct diazo reaction, this method slightly overestimates conjugated bilirubin. Therefore, a direct-reacting bilirubin concentration of <15% of total bilirubin is considered normal although normally only up to 4% of serum bilirubin is conjugated. The fraction of

bilirubin that is covalently bound to albumin also gives a direct reaction (182). As the irreversibly protein-bound bilirubin is cleared slowly from serum after relief of biliary obstruction, the finding of direct-reacting bilirubin during this period may give a false impression of continued biliary obstruction.

### 69.7.2 Chromatographic Analysis of Bilirubin as Intact Tetrapyrrole

For accurate identification of bilirubin and its conjugates for research purposes, methods based on thin-layer chromatography (180) or HPLC (116,183–185) have been developed. When the identification of specific sugar conjugates is not required, bilirubin mono- and diconjugates can be converted to mono- and dimethyl esters, respectively, by alkaline methanolysis before analysis (186). To measure the covalently albumin-bound fraction of bilirubin ( $\delta$ -bilirubin), HPLC is performed on incompletely deproteinated serum (182). The use of chromatographic methods of bilirubin analysis is generally limited to research laboratories.

### 69.7.3 Slide Test

The Ektachem slide test measures conjugated, unconjugated, and irreversibly protein-bound bilirubin using a diazo technique. One slide measures total bilirubin, and another specially coated slide allows only the free and reversibly protein-bound bilirubins to react with the diazo reagent; irreversibly protein-bound bilirubin can be estimated from the difference (187).

### 69.7.4 Transcutaneous Bilirubinometry

To assess the risk of severe neonatal hyperbilirubinemia, it is useful to evaluate the rate of increase of serum bilirubin levels during the first 24–48 h of life. Repeated estimation of serum bilirubin levels can be accomplished in a noninvasive manner by measuring the yellow color of the skin in reflected light, using computer analysis to circumvent the interference by underlying skin color (188,189).

## 69.8 BILIRUBIN IN BODY FLUIDS

### 69.8.1 Bilirubin in plasma

In the plasma, 96% of total bilirubin is unconjugated although the direct-reacting fraction, as determined by using diazo reagents, may slightly overestimate the conjugated fraction. During bilirubin overproduction, both unconjugated and conjugated fractions increase and their proportion remains unchanged. In contrast, reduced levels of bilirubin glucuronidating activity result in a lower proportion of conjugated bilirubin. In cases of intrahepatic cholestasis, biliary obstruction, or hepatocellular diseases, as well as in Dubin–Johnson and Rotor

syndromes, both conjugated and unconjugated bilirubin accumulate in plasma, and the proportion of conjugated bilirubin increases. Under these conditions, MRP2 is downregulated, reducing biliary excretion of conjugated bilirubin. Bile pigments accumulating in hepatocytes may be pumped out into plasma by alternative pumps (e.g. MRP1 and MRP3), which are upregulated during cholestasis. Following prolonged accumulation of conjugated bilirubin, a fraction of the pigment binds to albumin irreversibly. This fraction, termed  $\delta$ -bilirubin, gives a direct diazo reaction and can be identified by chromatographic analysis. After resolution of biliary obstruction or intrahepatic cholestasis,  $\delta$ -bilirubin may linger in plasma for several weeks because it is not taken up by hepatocytes or excreted in the urine (190).

### 69.8.2 Bilirubin in Bile

In human bile, over 80% of bilirubin is diglucuronide, with only approximately 4% being unconjugated bilirubin. When UGT1A1 activity is absent, as in the case of Crigler–Najjar syndrome type I, little or no bilirubin glucuronides are excreted in bile. In Crigler–Najjar syndrome type II or Gilbert syndromes, in which hepatic UGT1A1 activity is lower than normal, proportions of bilirubin monoglucuronide and unconjugated bilirubin increase in bile. The presence of a significant amount of conjugated bilirubin in bile reliably differentiates Crigler–Najjar syndrome type I from Crigler–Najjar syndrome type II (see later).

## 69.9 DISORDERS OF BILIRUBIN METABOLISM

Hyperbilirubinemia may result from increased bilirubin production, reduced uptake from the circulation, abnormal intracellular storage, deficiency of UGT1A1 activity, or biliary excretion of bilirubin. In many acquired clinical disorders, such as hepatitis or cirrhosis, several steps of this process are affected. In contrast, in inherited disorders of bilirubin metabolism, a specific step of bilirubin throughput may be involved. From the standpoint of bilirubin metabolism, these disorders may be classified into those that cause unconjugated hyperbilirubinemia and those associated with significant retention of conjugated bilirubin in serum.

### 69.9.1 Metabolic Disorders Causing Unconjugated Hyperbilirubinemia

**69.9.1.1 Neonatal Hyperbilirubinemia.** Serum bilirubin levels are higher in newborns compared to those in normal adults, with obvious jaundice occurring in about 50% during the first 5 days of life. Normally, serum bilirubin concentrations increase from 1–2 mg/dL at birth to a peak of 5–6 mg/dL in about 72 h, and subsequently decline to <1 mg/dL in 7–10 days (129).

In normal newborns, serum bilirubin is predominantly unconjugated. Exaggeration of this physiologic jaundice raises the concern of bilirubin-induced neuropathy. Serum bilirubin concentrations reach 10 mg/dL in about 16% of newborns, and the level exceeds 15 mg/dL in 5% (192). Jaundice of the newborn results from an increased bilirubin load and a lower capacity of the liver to dispose of bilirubin. Exaggeration of these factors and/or superimposition of additional mechanisms may result in a pathologic level of hyperbilirubinemia. The mechanisms of neonatal jaundice were briefly considered here.

**69.9.1.1.1 Increased Bilirubin Load.** Bilirubin production, as measured by carbon monoxide production, is increased in the newborn period (193). The excess bilirubin is derived from erythroid and nonerythroid sources and from shortened erythrocyte half-life (194). Rh incompatibility between mother and fetus used to be a common cause of severe neonatal jaundice before treatment of the mother with anti-Rh immunoglobulins became available (72). ABO blood group incompatibility continues to be a common cause of exaggerated neonatal hyperbilirubinemia (196). Sick cell disease, hereditary spherocytosis, and toxic or allergic drug reactions are common causes of hemolytic jaundice in the newborn period. Excessive bilirubin production can result from ineffective erythropoiesis, as in thalassemia, vitamin B12 deficiency, and congenital dyserythropoietic anemias. In cases in which the rate of bilirubin production exceeds the bile canalicular excretory capacity, conjugated bilirubin may accumulate in the serum (197).

**69.9.1.1.2 Low Hepatic Bilirubin Uptake.** During the first few days of life, the rate of hepatic uptake of bilirubin is lower than that in adults. The low uptake rate may be related to low levels of cytosolic GSTs (199), which increase net bilirubin uptake by binding bilirubin and thereby reducing its efflux. Delayed closure of the ductus venosus may permit portal blood, which is enriched in conjugated bilirubin from the intestine, to bypass the liver.

**69.9.1.1.3 Reduced Bilirubin Glucuronidation.** Only 1% of the normal adult level of hepatic UGT1A1 activity is present at birth (200). Postnatal maturation of UGT1A1 is birth related, and increases rapidly to adult levels by 14 weeks, regardless of the gestational age at birth (201). In some disorders, UGT1A1 activity is inhibited by some inherited factor(s).

**69.9.1.1.4 Maternal-Milk Jaundice.** Serum bilirubin levels in breast-fed infants are, in general, higher than in formula-fed babies (202), and, in some cases, may increase to 15–24 mg/dL by the age of 10–19 days (203). The unconjugated hyperbilirubinemia may promptly disappear when breast-feeding is discontinued. If breast-feeding is continued, the hyperbilirubinemia may last for weeks. Maternal-milk jaundice is usually benign (203), but kernicterus has been reported in rare cases (204). The maternal milk contains an inhibitor of UGT1A1

activity in this syndrome (203). It has been postulated that polyunsaturated free fatty acids produced by the action of lipolytic enzymes present in some maternal milk samples may be responsible for the inhibition of the transferase (205). Consistent with this notion, the inhibitory effect of maternal milk on bilirubin glucuronidation increases on storage and is destroyed by heating at 56°C (205). Mild maternal-milk jaundice may resolve despite continuation of breast-feeding.

**69.9.1.1.5 Maternal-Serum Jaundice.** This syndrome, associated with moderate to severe unconjugated hyperbilirubinemia (8.9–65 mg/dL) within the first 4 days of life, was described by Lucey, Arias, and associates (207,208). The syndrome is thought to be caused by an unidentified inhibitor of UGT1A1 present in the serum of mothers of these infants. The jaundice may persist several weeks and is occasionally associated with kernicterus.

**69.9.1.1.6 Decreased Canalicular Bilirubin Excretory Capacity.** Maturation of canalicular excretion processes may take longer than does the maturation of uptake and conjugation. Therefore, in the late newborn period, canalicular excretion becomes rate limiting in hepatic bilirubin disposition. In cases in which the bilirubin load is higher than normal, conjugated bilirubin accumulates in serum (209).

**69.9.1.1.7 Increased Intestinal Reabsorption.** Intestinal  $\beta$ -glucuronidase-mediated deconjugation releases unconjugated bilirubin in the intestine (210). Because of the lack of an established intestinal flora in the newborn, there is reduced bacterial degradation of bilirubin, resulting in an increased absorption of unconjugated bilirubin (210). A greater fraction of unconjugated bilirubin is absorbed from the intestine in infants fed with maternal milk.

**69.9.1.2 Hyperbilirubinemia Due to Bilirubin Overproduction.** Where liver function is normal, overproduction of bilirubin rarely increases serum bilirubin levels to >3–4 mg/dL. Common causes of overproduction of bilirubin include hematologic conditions associated with hemolysis, such as hereditary spherocytosis, and toxic or idiosyncratic drug reactions. Ineffective erythropoiesis that occurs in thalassemia and vitamin B12 deficiency, and a rare group of disorders called *dyserythropoietic anemias*, result in unconjugated hyperbilirubinemia of various degrees (211). In patients with hemolytic jaundice but normal liver function, a small amount of conjugated bilirubin produced in the liver may appear in the circulation (212), but the unconjugated:conjugated bilirubin ratio remains normal. In sickle cell anemia, a combination of hemolysis and liver abnormalities may lead to the accumulation of both unconjugated and conjugated bilirubin.

**69.9.1.3 Inherited Disorders of Bilirubin Glucuronidation.** Three inherited syndromes associated with a deficiency of bilirubin glucuronidation have been described. A near-complete deficiency of UGT1A1

activity results in Crigler–Najjar syndrome type 1. Severe but incomplete deficiency of UGT1A1 activity results in Crigler–Najjar syndrome type 2 also known as *Arias syndrome*. A mild reduction of UGT1A1 activity results in a common benign disorder, *Gilbert syndrome*, in which a mild and fluctuating unconjugated hyperbilirubinemia is the only significant clinical feature. Clinical and biochemical features of these syndromes are summarized in Table 69-1 and are described in this section.

**69.9.1.3.1 Crigler–Najjar Syndrome Type 1.** Crigler and Najjar (213) described this rare, recessively inherited syndrome in 1952 in six infants from three unrelated families. After the discovery of UGT, this syndrome was found to result from an absence of UGT1A1 activity (214). All patients had lifelong severe nonhemolytic unconjugated hyperbilirubinemia. Five of the six infants in the initial report died of bilirubin-induced encephalopathy within 15 months. The sixth patient remained free of brain damage until the age of 15 years, when kernicterus developed and death followed in 6 months (214). Another related patient remained without brain damage until 18 years of age, but then developed bilirubin encephalopathy and died at the age of 24 (215). The original family described by Crigler and Najjar had a high degree of consanguinity. Several members of this family had other recessively inherited disorders, such as Morquio syndrome, homocystinuria, metachromatic leukodystrophy, and bird-headed dwarfism. In subsequently studied families, the other recessively inherited disorders were not observed. Since 1952, several hundred other patients with Crigler–Najjar syndrome type 1 have been described in all races, and an autosomal-recessive inheritance has been established (214). Icterus is often the only finding on physical examination. However, in many patients, residual neurologic abnormalities, a

sequel to a previous episode of bilirubin encephalopathy, may be detected. With routine use of phototherapy and plasmapheresis for reversing acute bilirubin encephalopathy, many patients with Crigler–Najjar syndrome type 1 now survive through childhood. However, many survivors develop kernicterus around puberty or in early adult life (215). Use of phototherapy usually prolongs survival without encephalopathy to adolescence, and liver transplantation results in long-term survival (see later). Because of a relatively high concentration of unconjugated bilirubin in bile, pigment stones are common.

**69.9.1.3.1.1 Laboratory Tests.** Serum bilirubin levels usually range from 20 to 25 mg/dL, but may reach 50 mg/dL (213–215). Serum bilirubin is unconjugated, and there is no bilirubinuria. The concentration of serum bilirubin increases during intercurrent illnesses, and decreases on exposure to the sun or bright artificial light (41). The bile is paler than normal (217) and contains only small amounts of unconjugated bilirubin (218). The stool color is normal despite reduced fecal urobilinogen excretion (213). There is no evidence of hemolysis (217), and bilirubin is produced at a normal rate (219). Because bile canalicular transport is normal, BSP (213) and indocyanin green (220) and cleared normally from serum, and the biliary tree is normally visualized by cholecystographic agents.

**69.9.1.3.1.2 Liver Histology.** Liver histology is normal, except that, in several patients, bilirubin plugs were found to be deposited in bile canaliculi and bile ducts (213,218), probably resulting from biliary excretion of unconjugated bilirubin or its photoisomers.

**69.9.1.3.1.3 Abnormalities of Hepatic UGTs.** Hepatic UGT activity toward bilirubin is virtually absent in all patients with Crigler–Najjar syndrome type 1. In addition, many of these patients have reduction of the

**TABLE 69-1 Inherited Disorders Causing Unconjugated Hyperbilirubinemia**

	<b>Crigler–Najjar Syndrome Type 1</b>	<b>Crigler–Najjar Syndrome Type 2</b>	<b>Gilbert Syndrome</b>
Serum bilirubin concentration	340–850 $\mu$ M	<340 $\mu$ M	Usually <50 $\mu$ M
Routine liver function tests	Normal	Normal	Normal
Serum bile acid levels	Normal	Normal	Normal
Oral cholecystography	Normal	Normal	Normal
Liver histology	Normal	Normal	Normal
Bile proportion of monoglucuronide	Usually pale; contains small amounts of unconjugated bilirubin	Increased proportion of bilirubin monoglucuronide	Increased bilirubin
Hepatic BUGT activity	None	10% of normal or less	25–40% of normal
Effect of phenobarbital	None	Reduction by 25% or more	Reduction on serum bilirubin
Mode of inheritance	Autosomal recessive	Autosomal recessive	Autosomal recessive
Prevalence	Rare	Uncommon	Common, ~5% in general population
Prognosis	Kernicterus is the rule	Usually benign; kernicterus is rare	Benign

BUGT, bilirubin uridine diphosphoglucuronate glucuronosyltransferase.

level of glucuronidation of phenolic substrates (221). Immunologic analysis using monoclonal and polyclonal antibodies revealed variability of expression of UGT proteins in the liver of different patients with Crigler–Najjar syndrome type 1 (221).

Cloning and characterization of the human UGT1A locus in 1992 (135,140) has permitted the elucidation of the genetic basis of Crigler–Najjar syndrome type 1 (48,49,223). Because UGT1A1 is the only UGT isoform that contributes significantly to bilirubin glucuronidation, genetic lesions within any of the five exons comprising the UGT1A1 gene may lead to complete or near-complete loss of hepatic bilirubin glucuronidation. Such genetic lesions may consist of point mutations, deletions, or insertions within the coding region. Intronic mutations at splice donor or acceptor sites may lead to inappropriate splicing, resulting in loss of bilirubin–UGT activity (224). The genetic lesions may result in mutation of a single critical amino acid or deletion of segments of the enzyme. The various genetic lesions described in the literature (Table 69-2) have been reviewed recently (226–230). In cases where the genetic lesions are present in exons 2–5, all UGT isoforms expressed from the UGT1A locus are affected. However, when the mutation is located in the unique first exon of UGT1A1, only bilirubin glucuronidation is affected.

A large number of mutations can result in Crigler–Najjar syndrome type 1, and, in most cases, no particular mutation is common in a given community. An exception to this is seen in the Amish–Mennonite community, in which Crigler–Najjar syndrome type I is relatively common and all patients carry the same mutation (N. Roy Chowdhury et al., unpublished observation), indicating transmission of this mutation from a common ancestor through intermarriage within the small community.

Molecular diagnosis of Crigler–Najjar syndrome is achieved by amplification of the five exons of UGT1A1 and their flanking sequences by polymerase chain reaction (PCR) and sequence determination of the amplicons. The same strategy can be applied to perform prenatal diagnosis using chorionic villus samples as the starting material (232). Although in a great majority of cases, inheritance of genetic lesions from both parents is required for the manifestation of Crigler–Najjar syndrome, recently an instance of uniparental isodisomy has been reported in which both mutant alleles were inherited from the father (233). The mother's UGT1A1 genotype was normal. This case highlights the desirability of analyzing the genotype of both parents to determine the mode of inheritance of Crigler–Najjar syndrome.

The Gunn rat, and animal model of Crigler–Najjar syndrome type 1. Gunn rats are a mutant strain of Wistar rats that exhibit lifelong nonhemolytic unconjugated hyperbilirubinemia inherited as an autosomal-recessive characteristic (234) because of the deficiency of UGT activity toward bilirubin (235). The Gunn rat is the only animal model that develops bilirubin encephalopathy

spontaneously (236). Studies performed in Gunn rats have provided important information on bilirubin toxicity and have helped in developing new therapeutic modalities for hyperbilirubinemia, including cell transplantation and gene therapies (224,237–239). Gunn rats have a single guanosine base deletion in the common-region exon 4, which results in a frameshift, leading to a premature termination codon. As a consequence, 150 amino acid residues at the carboxy-terminal end of all isoforms encoded by the UGT1A locus are deleted (240) and their activities affected (241). However, UGT isoforms expressed from other UGT genes are unaffected (242).

**69.9.1.3.1.4 Treatment of Crigler–Najjar Syndrome Type 1.** Temporizing measures are directed at reducing serum bilirubin levels. Definitive treatment consists of partial- or whole-liver transplantation. New experimental therapies based on liver cell transplantation and gene therapy are currently being developed. These treatment modalities are briefly discussed here.

**69.9.1.3.1.4.1 Phototherapy.** Phototherapy is the most commonly used medical therapy for severe unconjugated hyperbilirubinemia (218). Banks of fluorescent lamps with devices for shielding the eyes, or “light blankets,” lower serum bilirubin levels by converting bilirubin IX $\alpha$ -ZZ to its photoisomers (see the section on bilirubin chemistry). Thickening of skin, pigmentation, and decreased surface area compared to body mass result in a diminution of effect of phototherapy beyond the age of 3 or 4 years (37,218).

**69.9.1.3.1.4.2 Plasmapheresis.** During neurologic emergencies, serum bilirubin concentration can be acutely reduced by plasmapheresis (218). Following removal of bilirubin that is tightly bound to plasma albumin, bilirubin is mobilized from tissue stores to the plasma. Attempts to remove plasma bilirubin by affinity chromatography on albumin-conjugated agarose gel columns were hindered in human subjects because of the removal of formed elements of blood (243).

**69.9.1.3.1.4.3 Orthotopic Liver Transplantation.** Presently, the transplantation of whole liver or a segment of the liver is the only available definitive treatment for Crigler–Najjar syndrome type 1 (244,245). Although this procedure is associated with some risk in these patients, it has been curative in several cases and has dramatically improved the outlook for these patients.

**69.9.1.3.1.4.4 Experimental Methods for Reduction of Serum Bilirubin Levels.**

**69.9.1.3.1.4.4.1 Inhibition of Heme Oxygenase Activity.** Noniron metalloporphyrins are strong inhibitors of microsomal heme oxygenase activity (23). Administration of tin-protoporphyrin has been shown to suppress neonatal hyperbilirubinemia in rhesus monkeys (246,247). Injection of tin-mesoporphyrin at 0.5  $\mu$ mol/kg three times a week for 13–23 weeks in two 17-year-old boys with Crigler–Najjar syndrome type 1 resulted in a modest reduction in serum bilirubin concentrations

(248). The place of this agent in the treatment of Crigler–Najjar syndrome type 1 is yet to be determined.

69.9.1.3.1.4.4.2 Oxidative Degradation of Bilirubin. Bilirubin oxidase from *Myrothecium verrucaria* (249) catalyzes the oxidation of bilirubin to a colorless product. Perfusion of human blood containing bilirubin through filters packed with immobilized bilirubin oxidase resulted in the degradation of 90% of the bilirubin per pass (249). When such columns were connected to the circulation of a Gunn rat, serum bilirubin levels are decreased by 50% in 30 min. There are some concerns, however, regarding the removal of formed elements of blood by these columns. Intravenous injection of bilirubin oxidase, linked to polyethylene glycol to increase its half-life in circulation, has resulted in significant reduction of serum bilirubin levels in Gunn rats, but only for a few hours (249).

69.9.1.3.1.4.4.3 Induction of P-450c. Induction of cytochrome P-450c activity results in increased oxidative degradation of bilirubin in Gunn rat liver, leading to the reduction of serum bilirubin levels. Several indoles present in cruciferous vegetables, such as cabbage, cauliflower, and Brussels sprouts, induce P4501A1 and P4501A2 in rat liver and intestine (250). Indole-3-carbinol, an inducer of P4501A2, is being studied for a potential therapeutic effect in Crigler–Najjar syndrome type 1 (250).

69.9.1.3.1.4.4.4 Replacement of UGT1A1 Activity. UGT1A1 activity is present in excess in normal liver. Therefore, partial replacement of UGT1A1 should reduce serum bilirubin levels in Crigler–Najjar syndrome type 1 to a nontoxic level. Transplantation of hepatocytes into the Gunn rat liver by portal venous infusion, injection into the splenic pulp (251), intraperitoneal injection of microcarrier-bound hepatocytes (85,252), or intraperitoneal implantation of alginate–polylysine-encapsulated hepatocytes (254) resulted in reduction of serum bilirubin levels in Gunn rats. After intrasplenic injection, a great majority of the hepatocytes rapidly translocate to the liver, where, in the absence of immune rejection, they survive and function throughout the life span of the recipient (255). On the basis of the experience gained from these preclinical studies, isolated allogenic human hepatocytes were transplanted into the liver of a patient with Crigler–Najjar syndrome type 1 through a catheter placed percutaneously into the portal vein (258,259). Transplantation of 7.5 billion hepatocytes resulted in the lowering of plasma bilirubin concentration by about 50% and permitted reduction of the duration of phototherapy. Two and half years later, bilirubin glucuronide excretion in bile continued, but serum bilirubin level gradually increased, probably because of increased bilirubin production or reduced effectiveness of phototherapy. The patient received an auxiliary liver transplantation, which has kept her serum bilirubin within normal limits (J. Roy Chowdhury, personal communication).

The clinical course of this case, as well as the experience with other patients who received hepatocyte transplantation (260), indicates that the number of adult hepatocytes that can be transplanted at a single procedure is not likely to be sufficient for curing inherited liver-based metabolic disorders (261). Moreover, there is an increasing shortage of good-quality donor livers for hepatocyte isolation (259,261). For these reasons, strategies are being explored to induce preferential proliferation of the transplanted normal hepatocytes over the mutant host cells. Since adult hepatocytes have a remarkable capacity to proliferate, massive repopulation of the liver by transplanted hepatocytes requires not only a proliferate stimulus to the engrafted cells, but also preparative manipulations of the host liver that prevent the replication of the host liver cells. Controlled hepatic irradiation in combination with a variety of mitotic stimuli is being evaluated for extensive repopulation of the liver by engrafted wild-type or genetically modified hepatocytes (141,264–266). Recent success in obtaining hepatocyte-like cells by differentiating human embryonic stem cells or induced pluripotent cells derived by reprogramming somatic cells, such as skin fibroblasts offer hopes for a renewable source of functional transplantable hepatocytes (24,268).

69.9.1.3.1.4.4.5 Gene Therapy. Supplementation with a normal *UGT1A1* gene is an attractive potential therapeutic modality. Methods for gene introduction into the liver using recombinant viruses or ligands that mediate receptor-directed endocytosis are being developed for this purpose. These approaches have been reviewed (224,269). In the ex vivo approach, liver cells isolated from a resected liver lobe of a mutant subject are established in primary culture and transduced with normal genes using recombinant retroviruses. The transduced cells are then transplanted into the subject, from whom the cells were obtained, thereby circumventing the need for immunosuppression. This approach resulted in modest reduction of serum low-density lipoprotein (LDL) cholesterol levels in LDL receptor–deficient rabbits (Watanabe Heritable Hyperlipidemic strain) (270) and in patients with familial hypercholesterolemia (271). However, advances in techniques of gene transfer (196) to the liver and ability to conditionally immortalize hepatocytes (272) should improve the possibility of success of ex vivo gene therapy. Recombinant adenoviruses are highly efficient in transferring genes to quiescent hepatocytes in vivo. Adenoviruses remain episomal and express transgenes very efficiently. Administration of these vectors to transfer human *UGT1A1* gene complementary DNA (cDNA) into Gunn rats resulted in rapid reduction in serum bilirubin levels.

However, these episomal vectors are eventually lost following cell division, and, because they are highly immunogenic, they cannot be administered repeatedly. The use of viral gene-deleted helper-dependent adenovectors can prolong the duration of transgene expression

and result in lifelong amelioration of jaundice in Gunn rats (273), but, for clinical gene therapy, the expression is not expected to be long enough to span the life of a human subject without repeated administration of the vectors. Repeated gene transfer using adenoviral vectors is possible by using generalized immunosuppression around the time of virus administration (274) or specific host tolerization to adenoviral proteins (275–278). However, this approach is difficult to translate into clinical application. In another approach, an immunomodulatory gene, such as adenoviral E3 or CTLA4-Ig, has been expressed along with the therapeutic transgene to prevent immune response against the cells infected with adenovirus (279,280). Coexpression of CTLA4-Ig, an inhibitor of costimulation of T lymphocytes by antigen-presenting cells, permits repeated administration of the adenovector, resulting in lifelong correction of jaundice in Gunn rats. However, the safety of abrogating host immunity toward adenoviruses, which are potential human pathogens, remains doubtful.

To avoid the need for readministration of gene-therapy vectors, we and others have explored the use of vectors that integrate into the host genome. Simian virus 40 (SV40) is a DNA virus of the papova family. Recombinant SV40 viruses have been developed by replacing the coding region for the T antigens with a target gene. These vectors can infect quiescent hepatocytes, are nonimmunogenic, and integrate into the host genome (281,282), permitting long-term expression of the transgene. Gunn rats treated with a recombinant SV40 virus expressing UGT1A1 showed significant long-term reduction in serum bilirubin levels (283). Because the recombinant virus does not evoke an immune response, the vector can be administered repeatedly.

Vectors based in nonrecombinant lentiviruses can integrate into the genome of both dividing and quiescent cells, such as hepatocytes. Administration of recombinant lentiviruses in utero on the nineteenth gestational day in Gunn rat embryos resulted in UGT1A1 expression in the liver and reduction of serum bilirubin levels in Gunn rats (284). Both recombinant SV40 and lentiviral vectors have a broad range of cellular targets and transduce many tissue types after systemic administration (283,284).

Nonviral, plasmid-based vectors are also being explored for gene therapy on the Gunn rat model. Both naked DNA and carriers containing ligands that are endocytosed via liver-specific receptors (e.g. the asialoglycoprotein receptor) are being evaluated (285–287). To enhance integration of the therapeutic transgene, some investigators are examining the feasibility of using the Sleeping Beauty transposon system, which results in the excision of the transgene at specific flanking sequences and splicing into the host chromosomal DNA (288). In a very different approach, oligonucleotides are used to correct single-base mutations or deletions utilizing the cell's intrinsic mismatch repair system (289). The nonviral

gene transfer or gene repair strategies hold great promise for safe gene therapy of inherited jaundice although, at their current state, these approaches are not efficient enough for immediate clinical application.

**69.9.1.3.2 Crigler–Najjar Syndrome Type 2.** Crigler–Najjar syndrome type 2 is also known as Arias Syndrome. Arias (8) reported a milder variant of the classical Crigler–Najjar syndrome, which is now termed Crigler–Najjar syndrome type 2, in which serum unconjugated bilirubin concentrations usually ranged from 8 to 18 mg/dL. During intercurrent illness, general anesthesia, or prolonged fasting, bilirubin levels could be as high as 40 mg/dL (291,292). Kernicterus is unusual in this group, but can be precipitated during episodes of exacerbated hyperbilirubinemia (8,217,291,292). As in Crigler–Najjar syndrome type 1, there is no evidence of hemolysis or other liver dysfunction. Crigler–Najjar syndrome type 2 is clinically differentiated from type 1 by >25% reduction of serum bilirubin after administration of enzyme-inducing agents (e.g. phenobarbital) and the presence of significant amounts of bilirubin glucuronides in bile although the proportion of bilirubin monoglucuronide exceeds 30% of total conjugated bilirubin (normal, ~10%) (292,293), reflecting a reduced hepatic UGT1A1 activity. The liver histology is normal, and UGT1A1 activity is usually reduced to approximately 10% of normal (292,293).

**69.9.1.3.2.1 Genetic Lesions.** Molecular genetic studies that have performed so far support an autosomal-recessive mode of inheritance (294). As in Crigler–Najjar syndrome type 1, the genetic lesions are found in the coding region of UGT1A1. However, in Crigler–Najjar syndrome type 2, these mutations always consists of a single amino acid transition that significantly reduces the UGT1A1 activity, without completely abolishing it. Table 69-3 lists the reported genetic lesions found in Crigler–Najjar syndrome type 2. In some cases, the mutation may increase the  $K_m$  for bilirubin (295). As the in vitro UGT1A1 assays are performed at high bilirubin concentrations, their measurements may overestimate the in vitro activity of the enzyme in these cases. The various lesions causing Crigler–Najjar syndrome type 2 have been reviewed (228).

**69.9.1.3.3 Gilbert Syndrome.** This disorder, associated with a mild, chronic, fluctuating unconjugated hyperbilirubinemia was described by Gilbert and Lereboullet (296). Although most patients present as isolated cases, familial incidence also has been noted (297).

**69.9.1.3.3.1 Clinical Features.** Gilbert syndrome is usually diagnosed in young adults who are incidentally found to have mild, predominantly unconjugated hyperbilirubinemia. Bilirubin levels may be elevated only intermittently and are usually <3 mg/dL, but may increase during intercurrent illness, stress, fasting, or menstrual periods (297). Mild icterus is the only positive finding on physical examination. Vague symptoms, such as fatigue and abdominal discomfort, reported by some patients

A slash separating two mutations indicates that the patient carried two different mutations on the two alleles.

N, normal; ND, not determined.

<sup>a</sup>Nomenclature of mutations is in accordance with den Dunnen and Antonarakis (85).

<sup>b</sup>In these cases, the hyperbilirubinemia was mild and the patients were classified as Gilbert syndrome.

<sup>c</sup>In all these cases, a heterozygous mutation was found to be the cause of the phenotype and a dominant-negative mechanism has been proposed to explain the hyperbilirubinemia.

may be manifestations of anxiety. Except for the predominantly unconjugated hyperbilirubinemia, routine blood tests are negative. Because canalicular excretion processes are normal, oral cholecystography allows visualization of the gallbladder. Liver biopsy is not routinely indicated, but, when performed, shows normal histology, except for a nonspecific accumulation of lipofuscin pigment in the centrilobular zones (298).

**69.9.1.3.3.2 Incidence.** Gilbert syndrome is perhaps the most common inherited disorder in man, the reported incidence ranging from 3% to 7% of the population (299,300). Distribution of serum bilirubin levels in the general population follows a skewed (301) or bimodal (299,300) pattern rather than a Gaussian distribution, and it has been proposed that subjects with Gilbert syndrome should be considered to represent one end of this spectrum. Therefore, the definition of Gilbert syndrome is somewhat arbitrary, making the determination

of its precise incidence difficult. Although it is possible to distinguish patients with Gilbert syndrome from the general population by determination of biliary bilirubin diglucuronide:monoglucuronide ratio and UGT1A1 activity in liver biopsy specimens, these tests are impractical for population studies. Because of the higher average serum bilirubin levels in males (299), Gilbert syndrome is diagnosed with much more frequency in males than in females (300). Gilbert syndrome is often recognized around puberty, which may be related to the inhibition of bilirubin glucuronidation by endogenous steroid hormones (302).

**69.9.1.3.3.3 Bilirubin Glucuronidation.** Hepatic UGT1A1 activity, as determined by in vitro assays, is present at a consistently low level (around 30% of normal) in Gilbert syndrome (303,304).

**69.9.1.3.3.4 Organic Anion Uptake.** In addition to reduced UGT1A1 activity, some patients with Gilbert

syndrome exhibit abnormalities of organic anion transport (306). However, based on studies of handling to bilirubin loads and the pattern of bilirubin conjugates secreted in bile, other investigators have suggested that the initial uptake of bilirubin is normal for Gilbert syndrome and the reduced plasma clearance may be explained by a decreased rate of glucuronidation only (307). The plasma disappearance of organic anions other than bilirubin (e.g. BSP or indocyanin green) may be abnormal in a minority of cases of Gilbert syndrome (308,309). No mechanistic basis for the association of decreased UGT1A1 activity and reduced organic anion uptake in these cases is known, and the coexistence of the two abnormalities may be merely coincidental.

**69.9.1.3.3.5 Diagnosis.** Gilbert syndrome is diagnosed in individuals with mild unconjugated hyperbilirubinemia without evidence of hemolysis or structural liver disease. Although hemolysis is not a feature of Gilbert syndrome, coexistent compensated hemolysis is found in many patients because increased bilirubin load results in clinically obvious jaundice (310). A presumptive diagnosis of Gilbert syndrome is made when mild unconjugated hyperbilirubinemia is noted on several occasions, and serum levels of alanine and aspartate aminotransferases, alkaline phosphatase,  $\gamma$ -glutamyl transpeptidase, and fasting and postcibal bile acid are all normal. Sequence determination of the promoter region upstream to exon 1 of UGT1A1 provides a simple means of diagnosis. If confirmation of diagnosis is required, chromatographic determination of the relative content of bilirubin monoglucuronide and diglucuronide in bile is of potential use in the diagnosis of Gilbert syndrome. Fasting or nicotinic acid tests provide suggestive data, but are not specific for Gilbert syndrome. Needle biopsy of the liver is not necessary for the diagnosis.

**69.9.1.3.3.6 Effect of Fasting.** Reduction of daily caloric intake to 400 kcal for 48 h results in elevation of serum bilirubin levels in all individuals (26). However, this response may be exaggerated in Gilbert syndrome (312). Fasting may induce hyperbilirubinemia by multiple physiologic mechanisms. Both increased bilirubin production (313) and reduced hepatic bilirubin clearance (314) have been reported. Reduction of hepatic UDPglucuronic acid content has been proposed as a mechanism of the exaggerated hyperbilirubinemic response to fasting in rats (315). However, because fasting also exacerbates hyperbilirubinemia in homozygous Gunn rats that lack UGT1A1 activity (316), reduction of bilirubin glucuronidation cannot be a complete explanation for fasting hyperbilirubinemia. Because of the overlap with the normal response to caloric deprivation (312), the fasting test does not reliably distinguish Gilbert syndrome from other hyperbilirubinemic states.

**69.9.1.3.3.7 Nicotinic Acid Tests.** Intravenous administration of nicotinic acid increases unconjugated hyperbilirubinemia, probably by increasing erythrocyte fragility, splenic heme oxygenase activity, and splenic

bilirubin formation (317). Nicotinic acid administration has been proposed as a provocative test for Gilbert syndrome; however, similar to fasting, it does not clearly distinguish patients with Gilbert syndrome from normal subjects or those with hepatobiliary disease (317).

**69.9.1.3.3.8 Bilirubin Conjugates in Bile.** As in Crigler-Najjar syndrome type 2, bile in Gilbert syndrome contains an increased proportion of bilirubin monoglucuronide (293), reflecting reduced hepatic UGT1A1 activity in these syndromes.

**69.9.1.3.3.9 Genetic Basis of Gilbert Syndrome.** Gilbert syndrome is associated with a variant TATAA box in the promoter upstream to exon 1 of UGT1A1. The normal TATAA element has the sequence A[TA]6TAA, whereas subjects with Gilbert syndrome are homozygous for elongation of the dinucleotide repeat, so that the sequence of the TATAA element is T[TA]7TAA (318). All subjects with Gilbert syndrome of white, black, or Asian Indian origin who have had genetic analysis were found to be homozygous for this variant promoter. Promoter-reporter studies show that an increased TATAA box length reduces UGT1A1 expression (318). Patients with the Gilbert genotype have been shown to have lower hepatic microsomal UGT1A1 activity (319). UGT1A1 alleles carrying the Gilbert-type TATAA element have been designated as UGT1A1\*28 (320). However, all subjects who are homozygous for the variant promoter do not exhibit the clinical phenotype, indicating that additional variables, particularly the rate of bilirubin production, are important for the manifestation of the phenotype. Notably, although the inheritance is autosomal (chromosome 2q37), women with this genotype usually do not manifest jaundice, probably because of lower daily bilirubin production. The gene frequency of the Gilbert-type promoter in the Western hemisphere is approximately 0.3. Thus, 9% of the general population is homozygous for this genotype. The gene frequency may be lower in Japan. Some mutations of the coding region of UGT1A1 may be associated with mild hyperbilirubinemia, compatible with the clinical diagnosis of Gilbert syndrome (321,322) (Table 69-3). These mutations have not been observed in populations other than those of Far Eastern origin. Some of these mutations have been reported to be dominant negative, suggesting that they can partially inactivate a normal allele (323).

Because of the high frequency of the Gilbert-type TATAA element in the general population, some heterozygous carriers of structural mutations may carry the Gilbert-type promoter on the structurally normal allele. This reduces the expression of the only structurally normal allele. Therefore, a combination of these mutations may give rise to intermediate levels of hyperbilirubinemia (324,325). This explains the long-standing observation that intermediate levels of hyperbilirubinemia are common among relatives of patients with Crigler-Najjar syndrome. This type of combination is a more common

cause of intermediate levels of hyperbilirubinemia than is homozygous mutation of the coding region in UGT1A1.

**69.9.1.3.3.10 Health Implications of Gilbert Syndrome.** Gilbert syndrome is generally considered innocuous, and its recognition is considered important mainly for reassuring the patient and the physician that no underlying liver disease is responsible for the mild hyperbilirubinemia. However, the clinical and epidemiologic significance of Gilbert syndrome is continuing to be unveiled. The UGT1A1\*28 genotype has been reported to be associated with accelerated or prolonged neonatal hyperbilirubinemia (326,327). In children with a combination of glucose-6-phosphate dehydrogenase deficiency and the UGT1A1\*28 genotype, neonatal serum bilirubin concentrations can rise to dangerously high levels (328). Patients with hereditary spherocytosis who also have the UGT1A1\*28 genotype may develop pigment gallstones early in life (329).

Although the mild hyperbilirubinemia associated with Gilbert syndrome should not cause any significant toxicity in adults and may indeed be cytoprotective by virtue of the antioxidant effect of bilirubin, the reduced expression of UGT1A1 activity may have some significant consequences. The pharmacogenetics of UGT1A1 polymorphism is receiving increasing attention (320). Oxidative paracetamol metabolism is associated with drug toxicity. Conflicting evidence has been reported for increased oxidative metabolism of paracetamol and its decreased glucuronidation in subjects with the UGT1A1\*28 allele (330,331). Gilbert syndrome is associated with a high incidence of diarrhea in patients treated with the anticancer drug, irinotecan (332).

**69.9.1.3.3.11 Animal Model.** Bolivian squirrel monkeys have higher serum unconjugated bilirubin concentrations and a greater hyperbilirubinemic response to fasting than does a closely related Brazilian population

(333,334). Plasma clearance of intravenously administered bilirubin, hepatic UGT activity toward bilirubin, and bilirubin diglucuronide:monoglucuronide ratio in bile are lower in the Bolivian population. In these respects, Bolivian squirrel monkeys are a model of Gilbert syndrome. Fasting hyperbilirubinemia is rapidly reversed by oral or intravenous administration of carbohydrates, but not by lipid administration (333).

## 69.9.2 Disorders Associated with Predominantly Conjugated Hyperbilirubinemia

Accumulation of conjugated bilirubin in serum may result from leakage of bilirubin glucuronides from hepatocytes or regurgitation from bile in inflammatory or ischemic diseases of the hepatocyte, and intrahepatic cholestasis or biliary obstruction. However, in specific disorders of organic anion storage or transport (e.g. Rotor and Dubin–Johnson syndromes), conjugated bilirubin may be retained in plasma in the absence of other evidence of liver dysfunction. Table 69-4 provides a comparison of the clinical and pathophysiologic features of these inherited disorders. In addition, there are inherited abnormalities of bile canalicular transport proteins that cause a group of disorders collectively termed progressive familial intrahepatic cholestasis. In another genetic condition, paucity of bile ducts leads to conjugated hyperbilirubinemia. A brief description of these disorders follows.

**69.9.2.1 Dubin–Johnson Syndrome.** A syndrome characterized by chronic nonhemolytic jaundice due to accumulation of conjugated bilirubin in serum and grossly pigmented, but otherwise histologically normal, livers was described by Dubin and Johnson (335) and by Sprinz and Nelson (336). Mild icterus is the only significant physical finding. Rarely, hepatosplenomegaly has

**TABLE 69-4 Inherited Disorders Causing Retention of Conjugated Bilirubin**

	Dubin–Johnson Syndrome	Rotor Syndrome
Serum bilirubin	Predominantly conjugated, usually 50–85 $\mu$ M, can be as high as 340 $\mu$ M	Predominantly conjugated, usually 50–100 $\mu$ M, occasionally as high as 340 $\mu$ M
Routine liver function tests	Normal except for hyperbilirubinemia	Normal except for hyperbilirubinemia
Serum bile salt levels	Normal	Normal
Plasma BSP retention	Normal at 45 min; secondary rise at 90 min	Elevated; but no secondary rise at 90 min
BSP infusion studies	T <sub>m</sub> very low; storage normal	T <sub>m</sub> and storage both reduced
Oral cholecystogram	Usually does not visualize the gallbladder	Usually visualizes the gallbladder
Urinary coproporphyrin excretion	Total—normal; >80% as coproporphyrin I	Total—elevated; ~50–75%, as coproporphyrin I pattern
Appearance of liver	Grossly black	Normal
Histology of liver	Dark pigments, predominantly in centrilobular	Normal, no increase in pigmentation areas; otherwise normal
Mode of inheritance	Autosomal recessive	Autosomal recessive
Prevalence	Rare (1:1300 in Middle Eastern Jews)	Rare
Prognosis	Benign	Benign
Animal model	Mutant TR <sup>-</sup> rats/mutant Corriedale sheep/Golden lion tamarin monkey	None

BSP, bromosulphthalein.

been observed (337,338). Although patients are usually asymptomatic, an occasional patient complains of weakness and vague abdominal pain. Serum bile acid levels are normal (339), and pruritis is absent. Serum bilirubin levels are increased by intercurrent illness, oral contraceptives, and pregnancy (339). Although the syndrome is occasionally recognized during the neonatal period (340), the diagnosis is most often made after puberty. In some cases, jaundice is first noticed during pregnancy or contraceptive use (339).

**69.9.2.1.1 Laboratory Tests.** Liver function tests, including serum bile acid levels, are normal (339). Serum bilirubin levels fluctuate. Usual levels range from 2 to 5 mg/dL, but levels as high as 20–25 mg/dL have been observed. Over 50% of total serum bilirubin is direct-reacting, and bilirubin is excreted in urine. Because the canalicular excretion abnormality includes a wide variety of non-bile-acid organic anions, oral cholecystography, even using a “double dose” of contrast material, usually does not visualize the gallbladder. However, visualization may occur 4–6 h after intravenous administration of meglumine iodipamide (Biligradin) (341). Grossly, the liver is black, and light microscopy reveals a dense pigment (342). Following infusion of 3H-epinephrine into mutant Corriedale sheep (an animal model for Dubin–Johnson syndrome), the isotope is incorporated into the hepatic pigment (343). The pigment differs from authentic melanin (344), but could be composed of polymers of epinephrine metabolites (345). Following liver disease, such as acute viral hepatitis, the pigment is cleared from the liver and reaccumulates slowly after recovery (346).

**69.9.2.1.2 Organic Anion Transport.** The hepatic secretion of bilirubin glucuronides, the leukotriene LTC<sub>4</sub>, reduced and oxidized glutathione, and numerous glucuronide and glutathione conjugates are disturbed in these patients (347,348). In contrast, bile acid secretion is unaffected. Hepatic storage is normal, and the transport abnormality is limited to canalicular excretion (349). After intravenous injection of BSP, plasma BSP concentration decreases at near-normal rate for 45 min, indicating a normal sinusoidal uptake process. However, in 90% of patients, plasma BSP concentration increases after this time, so that the concentration at 90 min is greater than that at 45 min because of reflux of glutathione-conjugated BSP from hepatocytes into the circulation (67). A similar secondary rise occurs after intravenous administration of bilirubin (351). Because the secondary rise of plasma BSP occurs in other hepatobiliary disorders as well (352), this phenomenon is not pathognomonic of Dubin–Johnson syndrome.

**69.9.2.1.3 Urinary Coproporphyrin Excretion.** In normal subjects, approximately 75% of the urinary coproporphyrin is isomer III, which is the precursor of heme. The total urinary coproporphyrin excretion is normal in Dubin–Johnson syndrome, but over 80% of the coproporphyrin is isomer I (353). The proportion of urinary coproporphyrin I in the urine of neonates is higher than

in adults, but the levels are not as high as in Dubin–Johnson syndrome (354). In unaffected parents or children of subjects with Dubin–Johnson syndrome, total urinary coproporphyrin excretion was reduced by 40% as compared to normal, because of a 50% reduction in coproporphyrin III excretion (355). The mechanism of the abnormal pattern of urinary porphyrin excretion and its relationship to the organic anion transport defect is not known. When the history and physical examination are consistent, the urinary coproporphyrin excretion pattern is diagnostic of Dubin–Johnson syndrome.

Organic anions other than bile acids are transported into the bile canaliculus from the hepatocyte against a concentration gradient by an ATP-dependent energy-consuming process, mediated by a protein that had been originally termed the canalicular multispecific organic anion transporter (cMOAT), and is now known as MRP2 or ABC-C2 (3,149,150,357,358) (Figure 69-1). These anions include conjugated bilirubin and other glucuronide- or glutathione-conjugated substances. MRP2 is one of the ABC transporters (357). Direct evidence for its involvement in canalicular transport came from the discovery of a frameshift mutation in the gene encoding in the TR– rat (154).

Despite the absence of MRP2, the serum bilirubin levels are only mildly elevated in Dubin–Johnson syndrome, suggesting alternative pathways for the secretion of bilirubin conjugates. Currently it is not known whether other canalicular transport proteins mediate the residual canalicular transport of bilirubin glucuronides in Dubin–Johnson syndrome. As discussed earlier, absence of MRP2 leads to accumulation of organic anions within the hepatocytes and upregulation of the expression of MRP1 and MRP3 in the basolateral domain of the hepatocyte plasma membrane. These and possibly other ATP-consuming pumps may contribute to the active export of unconjugated bilirubin and bilirubin glucuronides from the hepatocyte to plasma via the space of Disse (159).

**69.9.2.1.4 Genetic Basis and Inheritance.** Dubin–Johnson syndrome has been reported in all races and both sexes. There is a high incidence (1:1300) in Persian Jews (338), in whom it is associated with clotting factor VII deficiency (359). On the basis of the urinary coproporphyrin excretion abnormality, the inheritance pattern is clearly recognized as autosomal recessive (355). Dubin–Johnson syndrome is caused by mutations of the MRP2 (ABCC2) gene, causing a deficiency of canalicular MRP2 expression or function (152,154,360).

The human cDNA has been isolated on the basis of homology with rat MRP2 (153). The human MRP2 gene has been localized to chromosome 10q23–q24 (361), and the exon–intron organization has been elucidated (362,363). Several different mutations (Table 69-5) have been identified in this gene in patients with Dubin–Johnson (153,362–365). Mutations most commonly involve the crucial ATP-binding region. Mutation at an intronic splice donor site has also been identified in a patient with

<sup>a</sup>Nomenclature of mutations is in accordance with den Dunnen and Antonarakis (85).

Dubin–Johnson syndrome (364). Some mutations may lead to impaired glycosylation of MRP2, leading to premature proteasome-dependent degradation (366). The genetic analyses have confirmed an autosomal-recessive pattern of inheritance.

#### 69.9.2.1.5 Animal Models

**69.9.2.1.5.1 Mutant Corriedale Sheep.** In this mutant strain, biliary excretion of conjugated bilirubin, glutathione-conjugated BSP, iopanoic acid, and indocyanine green is decreased, whereas taurocholate transport is normal (367). The secretion of the organic cation procaine amide ethobromide is unaffected (3) and, interestingly, the secretion of unconjugated BSP is unimpaired (368). There is a mild hyperbilirubinemia, with 60% of the bilirubin being conjugated. The liver is pigmented but otherwise of normal histology (343). Total urinary coproporphyrin excretion is normal, with increased excretion of coproporphyrin isomer I and decreased isomer III excretion. In all these respects, the mutant Corriedale sheep is a model of Dubin–Johnson syndrome.

**69.9.2.1.5.2 TR– Rats.** These rats have a metabolic defect strongly resembling that in people with Dubin–Johnson syndrome and the mutant Corriedale sheep. Biliary secretion of conjugated bilirubin and many other organic anions is impaired (369), and coproporphyrin I is the major porphyrin excreted in urine (370). The liver is not normally pigmented, but, when the rats are fed a diet enriched in tryptophan, tyrosine, and phenylalanine, intracellular pigment deposition can be demonstrated. Impaired excretion of anionic metabolites of tyrosine, phenylalanine, and tryptophan may result in their retention, oxidation, polymerization, and subsequent lysosomal accumulation in the liver (371). As in human Dubin–Johnson syndrome, TR– rats (372) and rats of the Eisai hyperbilirubinemic rats (EHBR) strain, which have a similar defect, absence of MRP2 (mrp2 in rats) in the canalicular membrane leads to impaired canalicular secretion of bilirubin and other glucuronides, the leukotriene LTC<sub>4</sub>, glutathione, and glutathione conjugates (347). Experiments with the rodent models showed that

bilirubin conjugates and bile acids are secreted into the bile canaliculus via different pathways. Bile acids with free 3-OH groups are transported by the bile salt export pump (BSEP), but 3-OH-conjugated bile acids are transported by mrp2, as evidenced by impaired secretion of bile acid conjugates in TR– and EHBR rats (373).

**69.9.2.1.5.3 A Non-Human Primate Model.** The Golden Lion tamarin monkey, which manifests conjugated hyperbilirubinemia, is another animal model for Dubin–Johnson syndrome (374).

**69.9.2.2 Rotor Syndrome.** Rotor, Manahan, and Florentin described several patients with chronic predominantly conjugated hyperbilirubinemia from two families (93). Hematologic tests and blood biochemistries were normal. Liver histology was normal and, in contrast to Dubin–Johnson syndrome, there was no pigmentation. The basic abnormality of this disorder is different from that of Dubin–Johnson syndrome (375,376). Rotor syndrome is harmless and is characterized by chronic predominantly conjugated hyperbilirubinemia without evidence of hemolysis (93,375,376). It is rare, but has been described in several races.

**69.9.2.2.1 Organic Anion Excretion.** After intravenous injection of 5 mg/kg BSP, over 25% of injected BSP is retained in serum at 45 min, but there is no secondary rise of plasma BSP level and conjugated BSP does not appear in the plasma (377). There is also marked plasma retention of intravenously administered unconjugated bilirubin (378) and ICG (379). Phenotypically normal heterozygotes have mild abnormal BSP retention at 45 min (377). In contrast to the findings in Dubin–Johnson syndrome, oral cholecystographic agents visualize the gallbladder in Rotor syndrome (380).

**69.9.2.2.2 Hepatic Storage.** Transport maximum and hepatic storage of BSP has been determined by a constant infusion technique (377). In Dubin–Johnson syndrome, the transport is markedly abnormal, but the hepatic storage capacity is normal. In contrast, in Rotor syndrome, the storage capacity was reduced by 75–90%, whereas the transport maximum was reduced by only

50% (377). The findings in Rotor syndrome are similar to those in “familial hepatic storage disease,” which is associated with predominantly conjugated hyperbilirubinemia and normal liver histology (381). These two disorders may represent the same pathophysiologic entity.

**69.9.2.2.3 Urinary Coproporphyrin Excretion.** In Rotor syndrome, total urinary coproporphyrin is increased two- to fivefold over normal. The proportion of coproporphyrin I in urine is approximately 65% of total (376). These findings are similar to those seen in many other hepatobiliary disorders (382), and distinguish Rotor syndrome from Dubin–Johnson syndrome. In a recent report, however, two brothers with clinical Rotor syndrome had over 80% of urinary coproporphyrins as isomer I (383). Obligate heterozygotes have a coproporphyrin excretory pattern that is intermediate between that of control subjects and patients with Rotor syndrome. By urinary coproporphyrin analysis, Rotor syndrome appears to be inherited as an autosomal-recessive characteristic (376). The urinary coproporphyrin abnormality may be due to reduced biliary excretion of coproporphyrins, with concomitant increase in renal excretion. The mechanism of the organic anion transport defect in Rotor syndrome is not known.

### 69.9.3 Hyperbilirubinemia Resulting from Inherited Cholestasis Syndromes

**69.9.3.1 Progressive Familial Intrahepatic Cholestasis.** These inherited disorders do not specifically affect bilirubin metabolism, but cause the retention of both unconjugated and conjugated bilirubin in plasma by affecting bile flow. Three life-threatening heterogeneous disorders, characterized by defective secretion of bile acids or other components of bile, may result in cholestasis of various degrees of severity and are collectively termed progressive familial intrahepatic cholestasis (PFIC) (384). Benign recurrent intrahepatic cholestasis (BRIC) is a disorder that is genetically related to PFIC I. These disorders usually present during infancy or childhood, and are often associated with growth failure and progressive liver disease. Several additional genetic cholestatic disorders have been described during the past few years. PFIC syndromes and the other inherited cholestatic diseases have been reviewed recently (385) and are discussed in brief here.

**69.9.3.1.1 Progressive Familial Intrahepatic Cholestasis Type I.** PFIC I was originally described in a family in the Amish-Mennonite community and was named Byler disease, after the family name of the first patient (386). The disease is associated with severe life-threatening cholestasis, and is caused by mutations in the P-type ATPase gene, FIC1 (also termed ATP8B1), which has been localized to chromosome 18q21 (163). FIC-1 couples the hydrolysis of ATP to the translocation of acidic phospholipids. How the mutation of FIC-1 causes cholestasis and abnormal bile acid

transport is understood only partially (387). Lack of FIC-1 may lead to diminished nuclear translocation of the nuclear receptor FXR (388). Cholestasis may result from consequent downregulation of the BSEP (Section 76.345.3.361.3).

**69.9.3.1.2 Benign Recurrent Intrahepatic Cholestasis.** This disorder was first described in 1959 (389). It presents in adolescence or early adulthood (390,391) with recurrent episodes of conjugated hyperbilirubinemia associated with malaise, anorexia, pruritis, weight loss, and malabsorption. Laboratory tests reveal biochemical evidence of cholestasis without severe hepatocellular injury (392,393). Such episodes last for weeks to months, followed by a complete return to normalcy clinically, biochemically, and histologically. In a given patient, recurrent attacks resemble each other in symptoms, signs, and duration. Liver histology reveals noninflammatory intrahepatic cholestasis without fibrosis regardless of the number and severity of attacks. During remission, liver histology returns to normal whether examined by light or electron microscopy (394).

Family studies suggest a recessive inheritance pattern. Surprisingly, this relatively benign disorder was also found to be associated with mutations in the *FIC-1* gene, other mutations of which cause the much more severe disorder PFIC I.

There is no specific treatment for BRIC. Liver transplantation has not been considered because of the episodic and nonprogressive nature of the disease.

**69.9.3.1.3 Progressive Familial Intrahepatic Cholestasis Type II.** This disorder resembles Byler disease clinically, but occurs in non-Byler families, mainly in the Middle East and Europe. It is caused by defects in the gene that codes for the sister P-glycoprotein (SPGP), also known as BSEP or ABCB11, which is a canalicular ATP-dependent transporter of bile acids from the hepatocytes into the bile (395). The BSEP gene has been localized to chromosome 2q24 (165). A large number of different point mutations in BSEP have been described in patients with PFIC II.

Although both PFIC I and PFIC II are associated with life-threatening cholestasis, serum  $\gamma$ -glutamyl transpeptidase levels are normal or nearly so in both disorders, which differentiate them from PFIC III (165,384). BSEP is expressed specifically in the liver and, as expected, liver transplantation ameliorates all manifestations of PFIC II.

**69.9.3.1.4 Progressive Familial Intrahepatic Cholestasis Type III.** PFIC III involves mutations in the multidrug resistance protein-3 P-glycoprotein (PGY3, also known as MDR3/ABCB4) (Figure 69-1). MDR3/ABCB4 is thought to transport phosphatidylcholine from the inner lipid leaflet of the bile canaliculus to the outer leaflet, thereby replenishing the phospholipid, which is continuously removed into the bile because of contact with bile acids. In the absence of phosphatidylcholine translocation, bile acids damage the canalicular

membrane, causing progressive destruction of small bile ducts (209,396). In contrast to the findings in PFIC I and II, serum  $\gamma$ -glutamyl transpeptidase activity is increased in PFIC III (384). MDR3/ABCB4 deficiency in humans has been associated with a wide spectrum of hepatobiliary disorders, including small-duct primary sclerosing cholangitis (397) and cholesterol gallstones (398). Interestingly, heterozygosity for nonsense or missense mutations of the MDR3/ABCB4 gene has been associated with the heretofore enigmatic familial intrahepatic cholestasis of pregnancy (399,400).

**69.9.3.1.5 Treatment.** The treatment options currently available for PFICs are limited. Experimental transplantation of normal hepatocytes in an *mdr2* knockout mouse model of PFIC III has resulted in massive repopulation of the liver with the transplanted cells, resulting in long-term amelioration of the phospholipid transport defect in that condition (401,402).

**69.9.3.1.6 Other Inherited Cholestatic Disorders.** The cholangiopathy of North American Indian childhood cirrhosis is caused by the genetic lesions of a gene (*CIRH1A*) that encodes a mitochondrial scaffold protein. This disorder resembles clinically extrahepatic biliary atresia, except that there is no biliary tract obstruction (403).

GRACILE syndrome, another form of potentially lethal intrahepatic cholestasis associated with fetal growth retardation, aminoaciduria, iron overload, and lactic acidosis (GRACILE), is caused by genetic lesions of another mitochondrial scaffold gene, *BCS1L* (404). Interestingly, although North American Indian childhood cirrhosis and GRACILE syndrome are both caused by mutations of genes expressing mitochondrial scaffold proteins, neither of these syndromes includes features of usual mitochondriopathy, such as central nervous system lesions or hepatocellular steatosis.

Alagille syndrome is a multisystem development anomaly affecting the hepatobiliary system, eyes, vertebrae (sagittal, cleft), heart, kidneys, and central nervous system (405). Most patients exhibit a characteristic facies. The central nervous system lesions can be secondary to malnutrition, but in patients with carefully corrected nutritional balance, intracranial bleeding is the most common central nervous system complication (406). The syndrome is inherited as an autosomal-dominant condition with markedly variable penetrance. Lesions of the Jagged1 (*JAG1*) gene, mapped to chromosome 20p12 (407), are responsible for this disease. Jagged-1 is a ligand of Notch, and plays a critical role in the Notch signaling pathway that is important in the normal development of various organs. In about 70% of the patients with Alagille syndrome, deletion or mutations of the *JAG1* gene can be found, the coding region being normal in the remaining patients. Interestingly, 50–70% of these mutations are de novo, and not found in the parents. Paucity of bile ducts, which was considered *sine qua non* for Alagille syndrome is found in only 89% of

cases (406). Liver transplantation is required eventually in 21–50% of patients who have hepatic symptoms in infancy.

Villin disease, related to lesions of the *VILLIN1* gene, was reported to be the basis of cholestatic disease in several children, who eventually developed cirrhosis, requiring liver transplantation (408).

## ACKNOWLEDGMENTS

This work was supported in part by the following grants: NIH DK 079017 (to NRC), Liver Research Core Center (P30-DK 41296), NYSTEM C024346 and C026440 (to JRC), and a research grant from Oxalosis and Hyperoxaluria Foundation (to NRC).

### Biographies

**Namita Roy Chowdhury**, PhD is a professor in the Departments of Medicine and Genetics at Albert Einstein College of Medicine, New York. Dr N Roy Chowdhury received her PhD in Physiology from Calcutta University, India and her postdoctoral training at the University of Chemical Biology, Calcutta, India. She joined the Marion Bessin Liver Research Center of Albert Einstein College of Medicine in 1977, where she rose through the ranks to full professor. Her research is focused on the molecular mechanisms inherited liver diseases, particularly diseases of bilirubin metabolism.

**Jayanta Roy Chowdhury**, MD, MRCP, AGAF is a professor in the Department of Medicine (Gastrointestinal and Liver Diseases) and Genetics at Albert Einstein College of Medicine, New York. Dr J Roy Chowdhury received his Medical degree from Medical College, Calcutta, India. He received his postgraduate clinical training at Mount Sinai Hospital Services, New York, State University of New York at Stony Brook, and Royal Infirmary, Edinburgh, Scotland, UK. Dr J Roy Chowdhury joined the Marion Bessin Liver Research Center at Albert Einstein College of Medicine in 1975. He is the Scientific Director of the Cell Culture and Genetic Engineering Core of the Liver Research Center and also of the Gene Therapy Core of Albert Einstein College of Medicine. Dr J Roy Chowdhury's research focuses on the molecular mechanisms of metabolic liver diseases, and gene-based and cell-based therapies of liver diseases.

### 70.1 INTRODUCTION

#### 70.1.1 Familial Cancer and Cancer Genetics

All cancers are caused by abnormalities in genes. However, most cancers are not caused by *inherited* genetic disorders; most of the mutations in a cancer are somatic, acquired mutations. Familial clusters of cancer may be caused by shared environmental exposures, or by a germline mutation that creates an unusual sensitivity to ordinary environmental exposures. In some instances, the germline mutations facilitate the accelerated accumulation of somatic mutations, which helps to overcome statistical considerations that make it unlikely for any individual cell to accumulate the critical combination of mutations to overcome normal restraints on growth. In some instances, an inherited defect occurs in a tumor suppressor gene that is critical in regulating cell proliferation, such as the germline defect in the adenomatous polyposis coli (*APC*) gene. In other instances, a germline mutation occurs in a gene involved in maintaining the integrity of DNA. Inactivating germline mutations in the DNA mismatch repair (MMR) genes (*hMSH2*, *hMLH1*, *hMSH6* or *hPMS2*) cause Lynch syndrome, and biallelic mutations in the *MUTYH* gene cause a form of colonic polyposis.

In the cases of the *APC* gene or the DNA MMR genes, the inherited defect almost always occurs in one of the two alleles. This creates a situation in which the familial pattern of disease inheritance is autosomal dominant (i.e.

inheriting one mutant allele is sufficient for the predisposition to multiple colonic polyps), but mechanistically, the disease is actually recessive, and requires a second, “somatic” mutation of the other allele for the neoplasm to develop. This chapter reviews the general pathways by which certain gastrointestinal (GI) cancers develop, and focuses on germline mutations that predispose to the more dramatic, syndromic forms of familial GI cancer.

#### 70.1.2 Gastrointestinal Cancer

The GI tract is the site of more malignant tumors than any other organ system in the human body, which is one reason that much is known about genes that predispose to these cancers. The incidence of cancer in each organ of the GI tract varies enormously worldwide (1). The wide variations seen among different national groups appear to be explained almost entirely by environmental factors, principally dietary influences and the effects of chronic infections with different bacteria or viruses. For cancers of the esophagus, stomach, pancreas and hepatobiliary tree, environmental factors are overwhelmingly important, and familial factors play a minor role in carcinogenesis. However, in the colon and rectum, genetic considerations are somewhat more important, and are very important within the context of the developed world. In the extreme cases of familial adenomatous polyposis (FAP) and Lynch syndrome (or hereditary nonpolyposis colorectal cancer (HNPCC)), the germline mutations have powerful effects

that essentially overwhelm the influence of the environment. These two diseases have led to important insights into the formation of tumors in general (2).

## 70.2 THE GENETICS OF COLORECTAL CANCER

### 70.2.1 Somatic Genetics of Colorectal Cancer

Colorectal cancer was the first of the solid tumors to have undergone a sufficient degree of genetic analysis for the pathogenesis of the disease to be conceptualized. A step-wise series of events occurs whereby activating mutations in oncogenes and inactivating events in tumor suppressor genes accumulate, which account for the gradual evolution of colorectal neoplasia and the spectrum of premalignant tumors found in the colon (3). *K-RAS* was the first mutated oncogene found in colorectal cancer (4,5). Several different genetic lesions are involved in the inactivation of tumor suppressor genes, whose normal function is to inhibit cell proliferation or in some way prevent the emergence of the neoplastic phenotype. Tumor suppressor genes are functionally recessive inasmuch as the inactivation of both alleles is required for tumorigenesis. The recessive nature of tumor suppressor genes is the essential feature that permits them to be responsible for the familiarity of cancer. Inheritance occurs by a germline mutation in one allele, which affects every cell in the body. The second allele becomes inactivated in a somatic cell later in the life of the affected individual. Typically, the germline mutation is phenotypically silent, but the allele is inactivated in every somatic cell, greatly increasing the likelihood of tumor development, and decreasing the age at which this is likely to occur. The wild-type allele from the unaffected parent undergoes an acquired somatic alteration, referred to as the “second hit.” Each cell type has genes that specifically regulate its growth, which is why germline mutations in genes lead to tissue-specific cancers.

**70.2.1.1 The *APC* Gene.** An understanding of the somatic genetics of colorectal neoplasia began with an observation that occurred at the interface between sporadic and hereditary disease. A patient was identified who had multiple congenital abnormalities and features of FAP or Gardner’s syndrome (6). The patient’s colon was carpeted with adenomatous polyps, and he had two cancers in his colon. None of his relatives had FAP. It was assumed that he was an index case of FAP, and his karyotype revealed an interstitial deletion on 5q13–q22 that was not present in either parent. This clue led to the mapping of the gene for FAP at 5q21–q22 (7), and somatic deletions were found at this locus in 20% of sporadic colorectal cancers (8).

In 1991, two groups collaboratively reported cloning the adenomatous polyposis coli (*APC*) gene at the 5q locus, identified germline mutations in this gene in families with FAP, and reported mutations at this locus in sporadic colorectal cancers (9–12). The *APC* gene

encodes a 15-exon 8.5-kb transcript with a predicted protein structure that was unique at the time. The *APC* gene plays a major role in controlling epithelial cell proliferation. Mutations at the *APC* locus occur early in sporadic colorectal tumorigenesis; as it is one of the earliest genetic alterations in the multistep process, loss of function of *APC* has been termed the “gatekeeper” of neoplasia in the colon (13).

Neoplasia in the colon usually begins as a benign adenoma and, because of genomic instability that occurs along with progressive growth, additional mutations occur that permit the malignant phenotype to emerge. *APC* mutations are found in 63% of adenomas, including even the smallest of them (14). Most of the germline (and somatic) mutations create premature stop codons (nonsense mutations), or altered splice sites. Many of the mutations occur in the mutation cluster region in the fifteenth exon (Figure 70-1). This exon is a very long (>6000bp) open reading frame that accounts for about 75% of the *APC* transcript. Premature stop codons either lead to nonsense-mediated decay of the message, or result in the synthesis of a truncated *APC* protein. The multiple intestinal neoplasia (*min*) gene is the murine homolog of the human *APC* gene, and germline mutations at this locus cause multiple intestinal neoplasms in the mouse (15,16).

The *APC* gene product has multiple functions. One key role is to regulate intracellular concentrations of  $\beta$ -catenin (17), which can transactivate a cascade of genes involved in cellular proliferation, including *cyclin D*, *MYC*, *PPAR $\delta$*  and others. When the *APC* gene product is expressed in a cultured colon cancer cell line lacking wild-type *APC*, apoptosis ensues (18). The functions of  $\beta$ -catenin are complex, as this protein also participates in the intercellular adhesion junction (19,20). The earliest

**FIGURE 70-1** The *APC* gene germline and somatic mutations are depicted in FAP and non-FAP patients: 68 germline mutations in FAP patients and 241 somatic mutations in colorectal tumors from FAP and non-FAP patients are arranged on the *APC* sequence. Only the shaded regions were analyzed in this study. (From *Cancer Research* 1994, 54, 3011.)

colorectal neoplasms (adenomas) are characterized by excessive proliferation and the formation of a mass or polyp, which corresponds to at least some of the expected results of unregulated  $\beta$ -catenin expression. The APC protein is not expressed in the normally proliferating cells that are located at the base of the colonic crypt (21). APC protein is expressed as a function of colonic epithelial differentiation, and in mature epithelial cells it interacts with  $\beta$ -catenin, which leads to its phosphorylation and degradation. Loss of APC function usually occurs as a consequence of premature truncation, although more limited deletions of the APC-binding domain may be sufficient for loss of function (22). Missense mutations typically do not inactivate APC. In many of the colon cancers in which inactivating APC mutations cannot be found, stabilizing mutations in  $\beta$ -catenin that confer resistance to degradation by APC binding occur (23). Epigenetic silencing of the APC gene also occurs via hypermethylation of its promoter region (24,25). Hypermethylation-associated gene inactivation occurs in the promoters of numerous tumor suppressor genes, and is an important mechanism for tumor development (26).

**70.2.1.2 The K-RAS Gene.** The K-RAS-2 oncogene was among the first altered genes to be recognized in colorectal cancer (4,5,27). The *c-K-RAS-2* proto-oncogene is located on chromosome 12p; the gene product has GTPase activity and is a molecular switch for certain signal transduction pathways, some of which control growth and differentiation. Point mutations at codons 12, 13 and 61 frequently occur in colorectal cancer and, based on the three-dimensional structure of the *c-H-RAS* oncogene, these three amino acids interact with the phosphate groups of GTP. Critical mutations at these codons interfere with the regulation of the signal transduction, and deregulate cell growth (28). K-RAS-2 mutations occur in about half of benign adenomatous polyps in the colon (29), and it has been suggested that specific mutations at codon 12 may be associated with more aggressive tumor types (30,31). It appears that mutations in the APC gene are permissive of a neoplastic phenotype in the colon, whereas a RAS mutation in a cell might serve to facilitate additional clonal expansion. Although not an initiating event, RAS gene mutations appear to occur relatively early in the process of colon carcinogenesis, and copies of the mutated genes may be found in the stool or colonic effluents of patients with early disease, sometimes even in the absence of detectable colorectal neoplasia (32). Interestingly, RAS gene mutations in the absence of APC inactivation are found in hyperplastic polyps of the colon, which are not neoplastic, and not considered precursors of cancer, underscoring the importance of the sequence of the acquisition of mutations in carcinogenesis (33).

**70.2.1.3 Allelic Losses in Colorectal Cancer.** Vogelstein et al. (34) used restriction fragment length polymorphism (RFLP) analysis to search for allelic losses in colorectal carcinomas. In 56 paired specimens of normal colonic tissue and carcinoma studied with probes targeting most of

the chromosomal arms, 53 tumors demonstrated some degree of allelic loss or loss of heterozygosity (LOH). Some tumors lost a greater fraction of their allelic arms than others, and certain chromosomal arms—notably 17p and 18q—were lost in more than 75% of the tumors. Other allelic sites, namely, 1q, 4p, 5q, 6p, 6q, 8p, 9q, 18p and 22q, were lost in 25–50% of tumors. The recognition of frequent allelic loss in colorectal cancer led to a search for putative tumor suppressor genes on these chromosomes. The mechanism involved in this process remains incompletely understood and controversial. Several candidate mechanisms for chromosomal instability have been proposed (35). Importantly, the amount of allelic loss, expressed as “fractional allelic loss,” correlated with a more lethal outcome (36).

**70.2.1.4 The p53 Gene.** The *p53* gene on 17p was initially thought to be a possible oncogene (37). Colorectal cancers were found to have loss of one copy of *p53* in 75% of tumors, and the remaining allele was found to be mutant, fulfilling the prediction that biallelic losses would be required of tumor suppressor genes in cancer (38). Subsequently, *p53* mutations and deletions have been found in diverse types of tumors, including most of the common solid tumors in humans. It is currently thought that *p53* mutations may occur somewhat early in the tumor progression scheme, and that deletion of the wild-type allele occurs as a later event. A family of *p53* genes has been identified, and overlapping functions may complicate a simple interpretation of mutations in the *p53* gene (39). Using a combination of techniques, it has been observed that the allelic loss of markers linked to *p53* occurs either in focal carcinoma-in-adenoma (40), or precisely at the transition from adenoma to carcinoma (41). Families with germline mutations in *p53* (i.e. the Li-Fraumeni syndrome) are at increased risk for a variety of cancers, including sarcomas, breast cancer, and early-onset colorectal cancer (42).

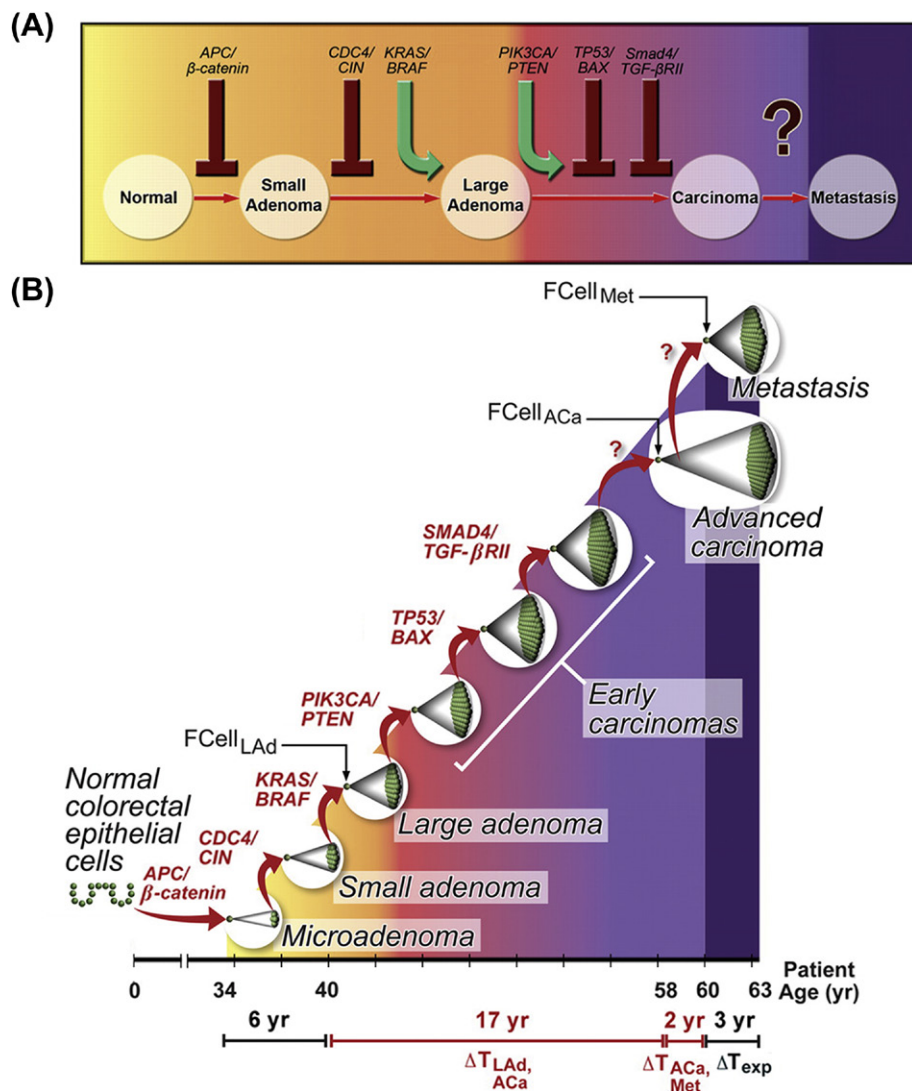

**70.2.1.5 Allelic Losses on 18q.** A high frequency of allelic loss in colorectal cancer was also noted on 18q (34). The first gene found at this locus was termed the “deleted in colorectal cancer” (*DCC*) gene (43), but the *SMAD4* gene also resides in this region (18q21.1) (44). Allelic loss at 18q appears to confer a worsening of five-year survival compared to patients who do not suffer this loss (45). Although this has been a somewhat controversial issue, there is evidence that the frequent chromosomal losses in this region and linkage with worse clinical outcomes are better explained by the loss of *SMAD* family genes, rather than *DCC* (46). Germ-line mutations in *DCC* have never been linked to familial cancer in humans or rodents. *DCC* knockout mice do not demonstrate abnormalities in intestinal growth, nor are they predisposed to cancer (47). Mice engineered to have mutations in both their *apc* and *smad4* genes (both of which are on mouse chromosome 18) have an enhanced neoplastic phenotype with larger and more malignant intestinal tumors (48). Moreover, mice with a

knockout of the *smad3* gene (which also corresponds to an 18q locus in humans) spontaneously develop aggressive, metastatic colon cancers (49).

**70.2.1.6 Multistep Carcinogenesis.** The concept of initiation and promotion, which was developed from animal models of skin tumorigenesis, has been replaced by the principle of multistep carcinogenesis (Figure 70-2A). An increase in the number of genetic lesions occurs during stepwise neoplastic progression. By analyzing the frequency of genetic alterations found at each stage of progressive neoplasia in the human colon, a model of multistep genetic damage has been proposed (3,50). The model proposes that a “genetic alteration” at the *APC* locus is an early and possibly initiating event in adenomatous tissue, which is the earliest identifiable colorectal neoplasm (14). *K-RAS* mutations are not found in tiny adenomatous polyps, but are

progressively more frequent in larger ones. *BRAF* mutations may substitute for *K-RAS* mutations, and appear to be involved in a separate “serrated pathway” that gives rise to neoplasms with somewhat different clinical features (33). Alterations on 18q are not common in small adenomas, but are more common in larger adenomas and those with more aggressive pathological appearances. As mentioned, biallelic losses of *p53* mediate the adenoma-to-carcinoma transition (41). By combining clinical and genetic data, it is possible to estimate the length of time required for multistep carcinogenesis to evolve in the colon (51). These estimates predict that it may take ~17 years for a large benign tumor to evolve into an advanced cancer, but less than 2 years for metastatic clones to arise within the cancer (Figure 70-2B).

**70.2.1.7 Genomic Instability.** Before 1993, attention had been focused on the identification of activated

**FIGURE 70-2** Sequential, multistep colorectal carcinogenesis. A. Fearon and Vogelstein proposed in 1990 that the sequential accumulation of genetic alterations was responsible for the morphological changes seen in tumor progression in the colon. Normal colonic tissue is represented on the left, and the sequential appearance of hyperproliferative epithelium, benign adenomatous polyps, and carcinoma are indicated with progression to the right. B. Colorectal cancers evolve by genetic alteration (mutation in this example), followed by clonal expansion, the generation of novel, diverse clones, and successive waves of expansion. However, the generation of a uniquely advantageous genetic alteration is a rare event, accounting for the long periods of latency that occur during the evolution of a lethal colorectal cancer. FCell indicates Founder Cells for advanced carcinoma or metastasis. (From PNAS 2008, 105, 4283.)

oncogenes and inactivated tumor suppressor genes in colorectal cancer. However, it had long been suspected that a phenotype of increased mutability might be required to account for the number of mutations found in many cancers (52). In 1993, three independent groups (53–55) reported that widespread mutations occurred at simple repeat genomic sequences in approximately 15% of colorectal cancers. These signature mutations are caused by loss of the DNA MMR function, and the result is referred to as microsatellite instability (MSI). MSI is defined by a critical number of mutations at microsatellite sequences in the DNA of a tumor (56). These observations ultimately led to the identification of mutations in DNA repair genes, and to the genetic basis of Lynch syndrome, previously called hereditary nonpolyposis colorectal cancer or HNPCC (57). Tumors with MSI are usually either diploid or near-diploid, and the mutational signature includes point mutations and insertion/deletion mutations at mono- and dinucleotide repeats, rather than as large cytogenetically detectable deletions, duplications or chromosomal rearrangements. Most colorectal cancers have intact DNA MMR activity, but are aneuploid. This latter process is not understood, and is referred to as chromosomal instability, or CIN (35,58).

**70.2.1.8 CpG Island Methylation and Gene Silencing in Cancer.** Allelic losses, chromosomal rearrangements, and point mutations in the DNA sequence are frequent mechanisms for the loss of function of tumor suppressor genes. However, it has been found that methylation of cytosines at CpG islands, which are found around the 5' ends of about half of human genes, leads to transcriptional silencing of the gene. In part, this is a normal physiological process occurring with aging, but in some cancers, there is an excess of methylated promoters. Furthermore, certain tumor suppressor genes are methylated in a large fraction of cancers of certain organs (26). The phenomenon of excessive methylation in cancer has been termed the CpG island methylator phenotype, or CIMP (59), and is an important mechanism for tumor development. Some genes frequently methylated in CIMP cancers may be mutated in other tumors, or deleted in yet others. In fact, the *APC* gene can be inactivated by any of these three processes (24), and one can find both processes in the same tumor, since biallelic inactivation is required for loss of expression of tumor suppressor genes (25). Nearly one-third of colorectal cancers have little evidence of extensive CIN or MSI, and may be a result of CIMP (60). To make matters somewhat more complicated, essentially all sporadic colorectal cancers with MSI also have CIMP, and the MSI is a result of biallelic inactivation of the *hMLH1* gene due to promoter methylation (61).

**70.2.1.9 Somatic Mutations in Colorectal and Other GI Cancers.** One way to determine the spectrum of somatic mutations in tumors is to perform complete exomic or total genomic sequencing of the tumors, and this has been done for various types of cancer, including GI cancers. A number of important insights have been gained through this approach. First, the number of

point mutations in coding exons is surprising low: about 1 somatic mutation per megabase of DNA in colorectal cancers (62,63). Secondly, there is a relatively narrow range for the prevalence of somatic mutations among types of tumors (from about 0.12 to 4.21 per megabase), with a few outliers, such as DNA MMR-deficient tumors, which have 32.29 somatic mutations per megabase. In addition, among individual tumors, one finds occasional cancer genomes with >70 somatic mutations, and a large proportion of tumors with <10 (Figure 70-3) (62).

The mutational signatures for tumor groups are potentially enlightening. Colorectal and gastric cancers show a great propensity for C:G → T:A mutations, with the relative exclusion of other mutations, a fingerprint also shared with gliomas and melanomas. This spectrum stands in stark contrast to the broad spectrum of mutations found in lung, breast, renal and ovarian cancers (62). Although there is no experimental data to prove this, this mutational pattern is consistent with a failure of base excision repair to completely excise adducts created by oxidative stress, a relative failure of one part of the DNA MMR system, or perhaps an overwhelming of these repair systems by excessive proliferation of gut epithelium (see *MUTYH*-associated polyposis (MAP)). In any event, the signatures found in GI tract tumors are quite different from the patterns seen in other tumors (Figure 70-4).

Total exomic sequencing has also been used to compare individual colorectal or other cancers. A study of 11 colorectal cancers revealed that the mutational spectrum is so variable among tumors, that none are exactly alike, and only a very small number of mutations are common to all colorectal cancers (Figure 70-5). The same was true for breast cancers. Interestingly, the three most commonly mutated genes—*APC*, *KRAS* and *p53*—were the same genes initially identified with much less precise investigative techniques in the early 1990s (63). Studies of copy number variation reveal a very heterogeneous landscape, but the patterns of variation have yet to yield clinically relevant interpretations (64). This raises the vexing problem of how to find systemic therapies for widespread tumors when each is driven by a different set of mutated genes.

**FIGURE 70-3** Number of mutations in a human cancer. The number of somatic mutations (including base substitutions, insertion–deletion lesions, and complex mutations) per megabase of DNA in 210 human cancers. The number of mutations per megabase ranges from none to nearly 80, underscoring the diversity in human cancer. (From *Nature* 2007, 446, 154.)

**FIGURE 70-4** Mutational spectrum in human cancers. The mutational spectrum in a series of 10 different types of human cancer suggests that cancers of different organs evolve through different mutagenic exposures. Colorectal and gastric cancers share some similarities but are distinct from lung and breast cancers, for example. The predominance of C:G → T:A mutations suggests a potential mutational mechanism (see text). INDELS indicates insertion or deletion mutations. (From *Nature* 2007, 446, 154.)

## 70.3 FAMILIAL COLORECTAL CANCER

### 70.3.1 Familial Adenomatous Polyposis (FAP), and Related Syndromes

FAP is an autosomal dominant disease in which affected individuals develop a large number of adenomatous polyps, predominantly in the colon. Adenomatous polyps may also occur in the small intestine and, rarely, in the stomach. Gastric polyps are common in FAP, but most of these are the result of fundic gland hyperplasia, and

actually, gastric cancer occurs in ~0.5% of FAP patients (65). Adenomatous polyps may bleed, or grow and cause obstructive symptoms, but the principal concern is the development of carcinoma. Cancer is nearly an inevitable consequence of FAP, as these benign neoplasms slowly grow and are subject to the same fate as sporadic adenomas. In FAP, however, there are hundreds or thousands of adenomas that begin in the teenage years, making malignant conversion a likely consequence because of the large number of adenomas, and their early appearance. The polyps are typical adenomas, which individually have a

**FIGURE 70-5** The genomic landscape of human colorectal cancer. Eleven colorectal cancers were subjected to total exomic sequencing, and the results plotted in two dimensions, representing all chromosomes, end to end, beginning with chromosome 1p in the left rear corner. Individual tumors had unique sets of mutations, as illustrated in the “landscape,” and only a handful of mutations were common to many tumors (creating the “mountains” in the landscape) or fewer (creating “hills”). The heterogeneity of the mutational landscape helps explain the variations in microscopic appearance, clinical behavior and therapeutic responses of individual colorectal cancers. (From *Science* 2007, 318, 1108.)

relatively low likelihood of malignant progression. It is the very large number that overwhelms the low risk for cancer in each individual polyp.

FAP begins with the asymptomatic appearance of a small number of polyps that progressively increase in number. Most of the polyps remain small, even without treatment. Over time, the colon may become studded with polyps. All histological varieties of neoplasia may be seen, including tubular adenomas, tubulovillous and villous adenomas, and carcinoma. Hyperplastic polyps and other types of pathological variants do not occur more commonly than in the general population. The finding of more than 100 adenomatous polyps in a young (<30 year old) individual is almost always FAP.

**70.3.1.1 Germline Mutations in the APC Gene and FAP.** As mentioned in the section on somatic genetics of colorectal cancer, FAP is caused by a germline mutation in the tumor suppressor gene called *APC*, located on chromosome 5q. A patient with FAP is asymptomatic at birth and phenotypically normal. Polyps of the colon begin to develop in the prepubertal and pubertal periods, and 50% have adenomatous polyps by age 16 (66). Early

reports of FAP series, which included a large number of patients who were not screened for the disease, indicated that the average age for the development of cancer was 39 years, and for death from cancer 42 years (67). This suggests that in the setting of FAP there is a lag of at least 23 years from the first adenomas to the occurrence of cancers. Work performed in humans with FAP, as well as the experimental rodent model of FAP, indicate that both *APC* alleles are inactivated in the adenomas in this disease (68,69). However, the mechanism of losing the second allele might be more complicated than a simple LOH event, and remains to be fully understood.

Most FAP is caused by inactivating germline mutations in one allele of *APC*, either premature stop codons, altered splice sites, or genetic deletions. A few well-characterized familial clusters of dominantly inherited adenomatous polyposis do not have a detectable germline lesion in *APC*, but these could be due to sequence alterations in a regulatory portion of the gene, or another cryptic mutation. It has been observed that 20–30% of FAP patients had new mutations, but there is phenotypic variation within families, and family members with identical *APC* mutations can show a variable number of polyps. Moreover, there is an autosomal recessive form of FAP involving a separate gene (*MUTYH*-associated polyposis). Identification of presymptomatic FAP patients can be achieved using a blood test to analyze the *APC* gene (70). Because the gene is large, an in vitro transcription–translation (IVTT) assay was initially used commercially, but this is not the most sensitive approach to diagnosis, and has been replaced by direct sequencing of the entire gene, and analyses for deletions or rearrangement. Some genetic testing performed in the 1990s may have used the IVTT approach, which may have given spuriously negative results to some patients. Genetic testing by DNA sequencing is commercially available, and information regarding laboratories that perform this can be found by consulting the Internet site <http://www.genetests.org>.

**70.3.1.2 Gardner Syndrome.** Gardner syndrome was initially thought to be a variant of FAP, with colonic polyposis and additional extraintestinal manifestations such as osteomas of the cranium and mandible, subcutaneous fibromas and lipomas, abnormal dentition, small intestinal polyps, etc. However, the identification of *APC* gene mutations as the basis for families with Gardner syndrome, and the recognition that all the extracolonic manifestations could be found in most FAP patients led to the realization that there was no specific difference between patients labeled as Gardner syndrome and FAP. The term Gardner syndrome remains as a historical reference to Dr Eldon Gardner, but it does not designate a unique disease.

**70.3.1.3 Variable Clinical Expression of FAP.** The phenotype in FAP may be either more or less virulent, based in part on the location of the *APC* mutation. The gene comprises 15 coding exons, the first 14 of which are of typical size. However, the very large open reading

frame of the 15th exon is a target for mutations. Particular hazard is associated with a mutation cluster region in exon 15 between codons 1250 and 1464. This is the most common site for mutations in sporadic adenomas, and germline mutations here are associated with a “profuse” phenotype with >5000 adenomas (Figure 70-6). Patients with germline mutations immediately upstream or downstream to this region typically develop fewer polyps (71,72). Furthermore, the average age to develop colorectal cancer in the profuse type of FAP is less than that observed in the sparse type (34 vs 42 years) (73). The mechanism underlying this remains uncertain, but this raises the possibility that some mutant alleles may encode a protein that exerts a dominant negative effect on the wild-type allele inherited from the unaffected parent.

The variable phenotypic expression in FAP is consistent with the influence of environmental factors, the presence of modifier genes, or both (74). In the mouse model of FAP, a major modifying locus called *mom-1* has been identified, which can affect the expression of the tumor phenotype (75). The situation may be more complicated, as a “modifier of min” has been located on the mouse chromosome 4, which may influence the mouse phenotype (76). Moreover, mutations at this locus, which encodes secretory phospholipase A2, are not involved in the clinical expression of FAP in humans.

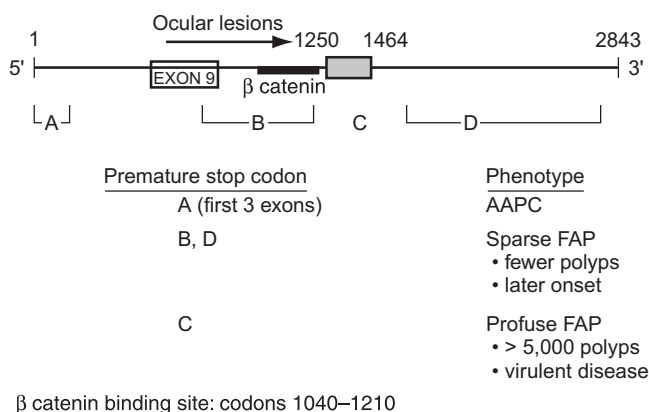

Congenital hypertrophy of retinal pigment epithelium (CHRPE) seen in FAP is rarely seen when the germline mutation of *APC* occurs in exons 1–7, but is frequently present when it occurs in exons 9–15 (77). A family has been reported with a germline mutation at the 3′ end

of the *APC* gene that results in a hereditary desmoid syndrome (78).

A genotypic variant of particular interest is when the premature truncation occurs in one of the first three exons of *APC*. The result is a form of the disease called attenuated adenomatous polyposis coli or attenuated FAP. In this condition, the number of polyps is smaller than in classic forms of the disease (79,80). In one large family with attenuated FAP, a considerable proportion of the members who carried the mutant gene had fewer than 50 polyps, and the average age for developing cancer was 54 years. However, several patients developed cancer in the absence of diffuse polyposis and, curiously, two members of the family had extensive polyposis. It has been demonstrated that the mechanism that accounts for the attenuation of the polyposis phenotype is the presence of an internal ribosomal entry site that permits transcription of the *APC* gene downstream of the mutation, skipping over the premature stop codon (81).

**70.3.1.4 Turcot Syndrome.** Turcot syndrome is a historical curiosity based on a few case reports of young patients with colon cancers or polyps and malignant tumors of the central nervous system. Most of these patients died at an early age, and often there was no apparent history of this disorder in the parents. Thus, inheritance was initially assumed to be autosomal recessive (82). Further attention was drawn to Turcot syndrome as a discrete entity when a family was found in which the manifestations were not linked to the *APC* gene (83). The issue was clarified by the characterization of 14 families with the manifestations of Turcot syndrome, of which 10 were found to have germline mutations in *APC* (84). The predominant brain tumor in those families was medulloblastoma. Furthermore, the relative risk (RR) of developing a cerebellar medulloblastoma in patients from FAP families was estimated to be 92 times that of the general population. Interestingly, in four other families, the brain tumors were glioblastoma multiforme, and three of these had germline mutations in one of the MMR genes, indicating that these patients actually had Lynch syndrome. Thus, the term Turcot syndrome does not actually indicate a unique disease, and these brain tumors in the presence of colorectal neoplasia in familial clusters or young patients should raise the possibility of either FAP or Lynch syndrome.

**70.3.1.5 The I1307K Variant of *APC* and Recurrent Adenomatous Polyps.** A curious wrinkle in the FAP phenotype is a predisposition to recurrent adenomatous polyps in the absence of diffuse polyposis, caused by a nontruncating sequence variation in *APC* termed I1307K (85). This might be considered a polymorphism in the gene, as no missense mutation has been identified, including this, which appears sufficient to cause FAP. The I1307K variation alters codon 1307 from isoleucine to lysine, but more importantly, converts the nucleotide sequence from AAATAAAA to A<sub>8</sub>, which is hypermutable and vulnerable to insertion or deletion mutations

**FIGURE 70-6** Germline mutations in the *APC* gene and the FAP phenotype. The *APC* gene is schematically depicted. Mutations occurring in segment A produce the attenuated FAP phenotype (AAPC). Mutations occurring from exon 9 to the 3′ end of the gene are associated with congenital hypertrophic retinal pigmented epithelium (CHRPE) lesions. Mutations occurring in segment C produce the profuse type of FAP with >5000 polyps, and earlier onset of polyps and cancer. Mutations occurring on either side of this (i.e. segments B and D) are associated with the sparse type of FAP, with a somewhat smaller number of polyps (~1000), and later onset of neoplasia. Segment C is also the most common site for acquired mutations in *APC*, and is situated immediately downstream of the β-catenin binding site.

during replication, which then creates a premature stop codon. This has been termed a premutation, which results in an increased risk of recurrent polyps and perhaps a two- to three-fold increase in the risk for colorectal cancer. This sequence variation occurs in 6% of Ashkenazi Jews and rarely presents outside of this population. This mild increase in predisposition to cancer can be managed by periodic colonoscopic screening, and does not ordinarily require prophylactic colectomy, as is required for severe forms of FAP. The clinical feature of I1307K is recurrent adenomatous polyps inherited in an autosomal dominant fashion. The I1307K allele requires a second, frameshift mutation within (or very close to) the  $A_8$  sequence for loss of function, and then a third mutation is required to inactivate the wild-type allele. The additional steps required are the likely explanation for the attenuated phenotype in carriers of this polymorphism, and the fragility of the  $A_8$  explains the increased risk for polyps. There have been contrary views on both the risk of cancer in individuals with this polymorphism, as well as the mechanism for inactivation of the APC alleles (86).

**70.3.1.6 MUTYH-Associated Polyposis (MAP): Autosomal Recessive FAP.** Some patients develop multiple colonic adenomas, but do not have a vertical family history of FAP; although there may be multiple polyps in more than one sibling, polyposis is not found in the parents. A systematic investigation of sibling clusters with multiple polyps in a British registry led to the discovery of an autosomal recessive genetic form of polyposis caused by germline mutations in the *MUTYH* gene (87), now called *MUTYH*-associated polyposis (MAP).

At least 1.3% of western European populations carry a missense mutation in one allele of the Mut Y homolog, *MUTYH*, initially called *MYH*, but changed as that name had been previously attached to another gene. *MUTYH* is a base excision repair (BER) gene, which participates in the process that repairs a mutagenic product of oxidative damage to DNA. The BER system can recognize 8-oxo-7,8-dihydro-2'-deoxyguanosine (8-oxo-dG), which is a characteristic by-product of oxidative damage. During DNA replication, guanines with this adduct may mispair with adenines rather than cytosines, leading to G:C → T:A mutations. Three human BER genes cooperate to repair oxidative damage—*MTH1*, *OGG1*, and *MUTYH*. The *MTH1* gene (the human Mut T homolog) prevents incorporation of the oxidized guanine into newly synthesized DNA. The Mut M homolog, *OGG1*, selectively excises 8-oxo-dG adducts from the DNA strand. The Mut Y homolog, *MUTYH*, is an adenine-specific DNA glycosylase, which can recognize adenines that are inappropriately paired with 8-oxo-dG, and removes them (88).

Families were found with an autosomal recessive pattern of multiple polyp development, and had no germline mutations in *APC*. Each adenoma in these patients had unique *APC* mutations, and the mutational spectrum revealed a mutational signature (G:C → T:A) consistent

with defective BER activity. These patients were found to have specific germline mutations in the *MUTYH* gene: Y165C and G382D. Owing to renumbering of the codons, these are now termed Y179C and G396D. These mutations were in evolutionarily conserved regions, and were judged likely to be pathogenic (89). About 1.3% of the western European population carries one of these mutations (90); these are absent from Korean, Japanese and Jewish populations. Y179C is a nearly inactive allele, whereas G396D is hypomorphic. Thus, patients with biallelic Y179C mutations have cancers detected at a mean age of 46 years, versus 58 years for the G396D homozygotes, and 52 years for the compound heterozygotes (91). About 90% of MAP patients from western European populations will have at least one of these two mutations (92).

A US study of patients with MAP reported this to be a relatively mild disease with 3–100 adenomatous polyps, and later onset of polyps compared to classic FAP (93). However, a group of 170 Dutch patients with colonic polyposis who had no germline mutations in *APC* were screened for *MUTYH* mutations, and biallelic mutations were found in 24%. Colorectal cancer was present at the time of diagnosis in 65% of the affected individuals, at ages ranging from 21 to 67. Patients with this disease in whom the polyps were counted were as likely to have 10–99 polyps as 100–1000, but none had <10, or >1000, adenomas. Several patients had gastroduodenal polyps, one had duodenal carcinoma, and there was a significant increase in breast cancers among women (94). In an extended study of 276 Dutch, English and German cases, duodenal adenomas were found in 17%, and the estimated lifetime risk for duodenal cancer was 4% (95).

Interestingly, monoallelic *MUTYH* mutations are somewhat more common in US colorectal cancer patients who are older than 50 years of age, than in those who are younger than 50 (93). To sensitively screen for this disease, one must know the allele frequency of mutant genes in the population under study. The mutations Y179C and G396D accounted for 81% of the mutant alleles in one study from Great Britain (88). Among patients with 5–100 adenomas, 6.4% were found to have biallelic *MUTYH* mutations, so this does not account for all the *APC* mutation-negative individuals with polyposis. However, it should be considered among those with late-onset polyposis of a mild-moderate variety. In the British study, the median age for diagnosis of the biallelic mutation carrier state was 50 years, and the median number of adenomas was 40. There is a reported increase in the risk of colorectal cancer among heterozygous carriers of *MUTYH* mutations, with a two-fold increase in incidence (96). Interestingly, there is a reduced risk of colon cancer-associated mortality in this disease compared to sporadic colorectal cancer (96,97).

Clinical testing of the *MUTYH* gene is commercially available. A reasonable strategy to screen for this disease is to test for the two common point mutations in

suspected patients. Once the first mutation is found, then the entire gene should be sequenced to find the second mutation. The requirement for biallelic mutations in the disease improves the likelihood that one will be found by screening for the common mutations first.

### 70.3.2 Lynch Syndrome, and the Nonpolyposis Familial Colorectal Cancer Syndromes

Lynch syndrome is an autosomal dominant disease that predisposes to cancers of the colon and other organs, and is currently defined on the basis of documenting a germline mutation in a DNA MMR gene. Lynch syndrome was first recognized in a “cancerous fraternity” by the University of Michigan pathologist, AS Warthin (98). The index family was followed up 58 years later in a classic paper by Lynch, who described the continued risk for cancer in the offspring of affected family members, which illustrated the autosomal dominant mode of inheritance and high degree of penetrance (99). Subsequently, a number of large families have been described and the syndrome is recognized by the features listed in Table 70-1. The possible diagnosis of Lynch syndrome is supported when the family history meets the Amsterdam Criteria, which have been modified over the years to accommodate the fact that colorectal cancer is just one of the manifestations of the disease. Lynch syndrome is caused by a germline mutation in one of several DNA MMR genes, and its hallmark is the presence of MSI in the tumor (56,57). In this disease, the manifestations are determined, to some degree, by which of the four MMR genes is responsible (Table 70-2).

**TABLE 70-1 Clinical Features of Lynch Syndrome**

Autosomal Dominant Inheritance
Increased risk for colorectal cancer (70 and 40% penetrance for men and women, respectively)
Colon cancers have increased frequency of unique pathological features: 60–70% occur in the proximal colon, early age of onset (average age 40–45 years), mucinous or signet ring pathological appearance, Crohns-like lymphocytic infiltration of the tumor, poorly differentiated appearance
Multiple colonic malignancies (both simultaneous and metachronous)
Increased incidence of endometrial cancer (40–60%)
Increased risk for tumors of:
Stomach (observed/expected (o/e) = 4.1, $P < 0.001$ )
Small intestine (o/e = 25.0, $P < 0.001$ )
Ovary (o/e = 3.5, $P < 0.001$ )
Kidney (o/e = 3.2, $P < 0.01$ )
Ureter (o/e = 22.0, $P < 0.001$ )
Brain tumors: glioblastoma multiforme
Increased risk for pancreatic and prostate cancers
No increase in the frequency of lung, breast, or prostate cancers

o/e = observed/expected frequency of the tumor.

**70.3.2.1 The Genetic Basis of Lynch Syndrome.** In 1993, three groups reported that a subset of colon cancers was characterized by a large number of mutations at microsatellite loci (53–55). At the same time, Lynch syndrome was linked to a locus on chromosome 2p in two large kindreds (100), and it was immediately recognized that MSI was present in the Lynch syndrome colorectal cancers (Figure 70-7). In a remarkably short period, four human

**TABLE 70-2 Clinical Features of Lynch Syndrome: by Germline Mutation**

Germline Mutation	Unique Genetic and Clinical Features
hMSH2	Classic features of Lynch syndrome; common locus Nearly all colorectal cancers are MSI-H IHC shows absence of staining for hMSH2 and hMSH6 proteins Many of the germline mutations are large deletions (missed by DNA sequencing) May be associated with Muir–Torre syndrome (with skin lesions)
hMLH1	Classic features of Lynch syndrome; common locus Most colorectal cancers are MSI-H, but some mutations do not show this (i.e. D132H) IHC shows absence of staining for hMLH1 and hPMS2 proteins Some missense mutations in hMLH1 do not lead to loss of hMLH1 immunostaining Some mutations in hMLH1 will lead to isolated loss of hPMS2 immunostaining Must be distinguished from more common, acquired loss of hMLH1 (promoter methylation), which may be associated with mutations in BRAF
hMSH6	Less common locus for Lynch syndrome Produces an attenuated disease with delayed onset of colorectal cancers (average age 56 years) Penetrance same as with hMSH2 and hMLH1, but average age 10–20 years later Increased penetrance for endometrial cancer (71% by age 70) Tumors may be MSI-H (86%), but occasionally MSI-L (14%) MSI testing less sensitive in endometrial cancers IHC shows isolated loss of hMSH6 staining in 90%; hMSH2 staining intact Some mutations retain immunoreactivity, but lose function Families often fail to meet Amsterdam criteria because of later onset of cancers
hPMS2	Less common locus for Lynch syndrome Attenuated disease with later onset of cancer (>50 years old) and reduced penetrance Most colorectal cancers are MSI-H IHC shows isolated loss of hPMS2 protein, with intact hMLH1, hMSH2, hMSH6 Germline mutation detection problematic because of multiple (20) pseudogenes that mask mutations in the true gene

IHC, immunohistochemistry; MSI, microsatellite instability.

genes were cloned that account for most of the germline mutations in Lynch syndrome (101–105). These genes are all homologous to yeast MMR genes and were termed *hMSH2*, *hMLH1*, *hPMS1* and *hPMS2*. However, linkage of *hPMS1* to familial cancer was spurious, and the gene is not considered to be a Lynch syndrome gene now. Subsequently, germline mutations in the *hMSH6* gene were linked to Lynch syndrome families as well (106–108). It has been proposed that both *hMLH3* (109,110) and *Exo1* (111) may be linked to familial colorectal cancer clusters, but convincing clinical evidence for these as Lynch syndrome genes is lacking (112–115). No Lynch syndrome families have ever been linked to germline mutations in the *hMSH3* gene. Thus, *hMSH2* and *hMLH1* are the “major” Lynch syndrome genes, and are the loci of mutation for most families with classic forms of the disease. *hMSH6* mutations less commonly cause Lynch syndrome,

and one sees an attenuated form of the disease with these mutations. *hPMS2* also appears to produce an attenuated form of the disease, and is linked to a smaller, but as-yet undetermined, number of these cases (Table 70-3) (116).

The population prevalence of Lynch syndrome has not yet been established for the United States and western Europe, but a crude estimate would be at least one per 300 (117), based on the lifetime prevalence of colorectal cancer in the United States (~5/100), the proportion of colorectal cancers with MSI (~15%), and an estimate of what proportion of tumors with MSI are a result of Lynch syndrome (20–25% of those). This would provide an estimate of ~1.9/1000, but a higher estimate would account for the incomplete penetrance of colorectal cancer in this disease, which is in the range of 70% for men but may be about 40%, or even less, for women. Studies using population-based sequencing of the major DNA MMR genes

### (A) Single mismatch

### (B) Exonuclease complex and resynthesis

### (C) Insertion/deletion loop and variations in MutL complexes

**FIGURE 70-7** The DNA MMR system. This system requires one pair of heterodimerized proteins (either *hMSH2*+*hMSH6*—or *MutSα*—as shown in the top panel or *hMSH2*+*hMSH3*—called *MutSβ*—as shown in the bottom panel) to recognize a mismatch error in newly synthesized DNA. The mismatch triggers a conformational change in which the dimer forms a sliding clamp on the DNA, sliding away from the mispair toward the DNA polymerase complex. A second dimer (consisting of *hMLH1* + *hPMS2* (*MutLα*, as shown on the top), *hMLH1* + *hMLH3* (*MutLβ*) or *hMLH1* + *hPMS1* (*MutLγ*; all three shown in the bottom panel)), which interacts with PCNA and Exonuclease 1 to facilitate the excision of the mismatch, and ultimately, resynthesis to repair the error. (From *Gastroenterology* 2010, 138, 2073.)

TABLE 70-3 Lynch Syndrome Genes

Human Gene	Bacterial Homolog	Chromosomal Location	Base Pairs in cDNA	No. of Exons	Protein Size (aa-Amino Acids)
hMSH2	MutS	2p16	2727	16	934aa (105 kDa)
hMSH6	MutS	2p15–16	4245	10	1360aa (160 kDa)
hMLH1	MutL	3p21.3	2268	19	756aa (85 kDa)
hPMS2	MutL	7p22	2586	15	862aa (96 kDa)

*hMSH2* and *hMLH1* yield lower estimates for the prevalence of Lynch syndrome, largely because it has not been possible to detect all the disease-causing mutations using current technologies. Sequencing these two genes yields likely disease-causing mutations in 26% of familial clusters of colorectal cancer (118). Even accepting these limitations, documentable Lynch syndrome accounts for at least 2.2% of all colorectal cancers (119). Mutation databases are available at <http://www.nfdht.nl>, which assist in the attempts to distinguish innocuous sequence variations from disease-causing mutations in the DNA MMR genes.

**70.3.2.2 Mechanism of Tumor Development in Lynch Syndrome.** The basis of tumor development in Lynch syndrome is the result of a failure of the DNA MMR system. This DNA repair system monitors replication mismatches that occur as a result of misincorporation of bases by DNA polymerase, and “loop-outs,” which are errors that occur at repetitive sequences (i.e. mononucleotide or dinucleotide repeats) during DNA replication (Figure 70-7). A number of proteins are involved in this process. Loss of either of the two major MMR proteins (*hMSH2* or *hMLH1*) results in a total loss of DNA MMR. These major proteins are necessary for stabilization of the repair complex through heterodimerization with minor DNA MMR proteins, *hMSH6*, *hMSH3*, *hPMS2* and possibly others (120).

Individuals with Lynch syndrome have a germline mutation that inactivates one allele of a DNA MMR gene. The presence of the second, wild-type allele provides sufficient levels of gene expression and protein function that MSI is not found in normal tissues unless there are biallelic germline mutations, which are rare. Monoallelic inactivation of a DNA MMR gene is associated with a normal phenotype, but with an increased risk of developing cancer. When a second alteration occurs that inactivates the wild-type allele in a cell of a target tissue, there is loss of DNA MMR activity, resulting in MSI.

MSI can be found in about ~15% of all colorectal cancers (53–55). Not all of these are Lynch syndrome tumors. Criteria have been established for the performance and interpretation of testing for MSI (121,122). An international consensus conference led to the adoption of a panel of five microsatellite markers, which is now widely accepted for investigation or clinical diagnosis (56). However, other microsatellite panels have been found to perform at least as well for the detection of MSI

colorectal cancers (123–125). Moreover, the selection of appropriate marker obviates the need to use matched normal DNA to determine the presence of MSI (125).

Two types of MSI can be found in colorectal tumors, from which important implications can be drawn. When two or more of five markers are mutated, the tumor is designated MSI-high (MSI-H). These tumors share the phenotype described for Lynch syndrome, with a characteristic pathology, a proximal colonic predominance, and a better prognosis. About 20–25% of these tumors come from patients with Lynch syndrome, and the other 75–80% arise from acquired hypermethylation of the promoter of the *hMLH1* gene, which is unrelated to familiality (61,126,127). When only one of the five microsatellite markers is mutated, the tumor is designated MSI-low (MSI-L). These tumors behave clinically like tumors that show microsatellite stability (MSS), in which none of the five microsatellites tested is mutated. The mechanism of MSI-L may be multifactorial, but nongenetic downregulation of the *hMSH3* gene has been shown to produce MSI-L. Loss of *hMSH3* activity shown by immunohistochemistry correlates with the presence of somatic mutations in tri- and tetranucleotide repeats (which has been termed EMAST, for elevated microsatellite alterations at selected tetranucleotide repeats) (128). EMAST can be found in ~60% of colorectal cancers, and this is sometimes reflected as MSI-L, which may occur with no mutations at mononucleotide repeats, and occasional mutations at dinucleotide repeats.

MSI permits a very substantial increase in the accumulation of mutations at simple repetitive sequences called microsatellites. Some microsatellites occur in the coding regions of genes that control the growth of colorectal cells. When these genes are inactivated in the setting of MSI, the progeny will undergo clonal expansion, leading to the formation of a neoplasm. Repetitive sequences are under negative evolutionary selection pressure in the genome because they are intrinsically unstable. Nonetheless, a few genes are in our genome in which a coding exon has a mononucleotide repeat of six or more, and many are mutated in MSI-H cancers. The microsatellites in the diagnostic panel may be functionally unimportant, and simply passengers that are not directly involved in carcinogenesis.

Once MSI-H has developed, a cell becomes hypermutable (but not necessarily neoplastic). It is the mutational inactivation of target genes that leads to abnormal growth behaviors. The initial target genes found in

**TABLE 70-4 Target Genes in Colorectal Cancers with Microsatellite Instability**

Gene	Repeat	Frequency in Colorectal Cancers
TGF- $\beta$ R2	A10	85–90% (MSI)
IGF 2R	G8	9% of MSI tumors, 1/8 Lynch syndrome tumors
Bax	G8	51–54% (MSI); 52% in Lynch syndrome tumors
MSH6	C8	33% in Lynch syndrome cancers
MSH3	A8	52% in Lynch syndrome cancers
E2F4	(CAG) <sub>n</sub>	65% (in all MSI cancers)
Caspase-5	A10	62% in MSI cancers
ACVR	A8	50–75% in MSI cancers
TCF-4	A9	?
PTEN	A6 (2)	?

MSI = microsatellite instability.

Other genes frequently mutated at several sites in tumors with MSI include APC,  $\beta$ -catenin and  $\beta$ 2-microglobulin.

association with the mutator phenotype were the transforming growth factor  $\beta$ <sub>1</sub>-receptor type 2 gene, which contains an A<sub>10</sub> sequence (129); the insulin-like growth factor 2-receptor, which contains a G<sub>8</sub> tract (130); the BAX gene, which contains a G<sub>8</sub> tract (131); and several of the minor DNA MMR genes (132). A variety of other genes may be mutated in MSI-H tumors, including APC, PTEN, XTNNB1, CASP7, E2F4, and TCF-4 (56,133,134) (Table 70-4). Many of these are genes involved in the regulation of cell proliferation or apoptosis, and represent tumor suppressor genes that are mutated in this unique carcinogenic “pathway.”

The hypermutability caused by loss of DNA MMR activity leads to a great increase in frameshift mutations at repetitive sequences, and when the sequence is in an exon it typically creates a downstream stop codon, and either makes a nonfunctional protein, or is degraded through nonsense-mediated decay. If the inactivated gene is involved in growth regulation in colonic tissues, there may be clonal expansion, the accumulation of more mutations, and a multistep carcinogenesis pathway parallel to that initially described by Vogelstein in 1988, but involving a fundamentally different mechanism of genomic instability and a different set of target genes.

**70.3.2.3 Clinical Features of Lynch Syndrome and “Familial Colorectal Cancer Type X”.** Lynch syndrome is clinically heterogeneous, and the term “hereditary nonpolyposis colorectal cancer” (HNPCC) is both inadequate and misleading. It has been suggested that the term “Lynch syndrome” be used for the familial cancer syndromes in which a germline mutation in a DNA MMR gene has been identified (135). This is to avoid inclusion of the well-characterized familial clusters of early-onset colorectal cancer that are not classic Lynch syndrome, and are not caused by germline mutations in DNA MMR genes (136). By comparison, true Lynch

syndrome families have an earlier onset of colorectal cancer and extracolonic cancers, and there are elevated risks for cancers of the endometrium, ovaries, urinary tract (particularly renal pelvis and ureter), stomach, pancreas, brain, and small intestine, when compared with the familial clusters of colorectal cancer not associated with a germline mutation in a DNA MMR gene. It has been suggested that the latter families should perhaps be termed “familial colorectal cancer—type X” (136). They have no increase in relative incidences of cancer in organs other than the colorectum, a lower penetrance for colorectal cancer, and a later onset of the cancers. Compared to the general population, the relative risk (RR) for colorectal cancer in Lynch syndrome is 6.1, compared with 2.3 for “syndrome X.” The mean age of onset of colorectal cancer is 48.1 in the relatives of patients with Lynch syndrome vs 60.7 for the relatives of those with “syndrome X.” This concept has been confirmed in a Spanish cohort of patients (137).

The increased risk for cancer in Lynch syndrome is organ specific, most pronounced for the colon and endometrium, but increased risks for cancer are seen for other organs (138,139). Importantly, there are no significant increases in breast, lung or prostate cancers in Lynch syndrome families, indicating that this syndrome does not lead to an increase in cancer for every organ (136). A hallmark of Lynch syndrome is the early age at which tumors develop: colorectal and endometrial cancers typically occur two or more decades earlier than would be expected in the general population. The disease is inherited as a classic autosomal dominant condition, based on the inheritance of a germline mutation in a DNA MMR gene.

It is recognized that incomplete penetrance of the phenotype can occur in Lynch syndrome. There have been individuals who have developed as many as five or six tumors in several different organs (140), but most affected individuals tend to develop one or two in their lifetime. The risk of developing a cancer is linear and continuously increases by about 1.6% per year (141–143). Cancer risks for specific organs have been variably estimated by different registries, and may vary according to the DNA MMR gene affected, the presence of modifier genes in the population being studied, and confounding environmental influences. Polymorphisms in putative modifier genes, including *cyclin D* (144), codon 72 of the *p53* gene (145), and in several carcinogen-metabolizing enzymes (146,147), are associated with earlier tumor onset. Single nucleotide polymorphisms (SNPs) at 8q23.3 and 11q23.1, not associated with specific genes have been linked with two- to three-fold increased risks for colorectal cancer in Lynch syndrome (148). Lifetime risks for colorectal cancer have been estimated to be as high as 80% (141,149), but as the ability to diagnose these families more carefully at the genetic level improves, the estimates are likely to fall. For example, using known germline mutations (instead of simply family history), it has been reported that male gene carriers have a colorectal cancer risk of 74% by age 70, whereas female

gene carriers have a risk of 30%. Overall cancer risks were also modified by gender in this study, and men had a 91% risk for any cancer by age 70 vs 69% in women. Women in this study had a 42% risk of endometrial cancer, which is greater than their risk for colon cancer (150). Moreover, as families are characterized on the basis of germline mutational analysis, there may be a shift toward later onset of cancer, since many of the initial family clusters (identified on the basis of family history) may be over-represented with the most severely affected families.

#### 70.3.2.4 Pathological Features in Lynch Syndrome.

The pathologic features of the cancers are unique in Lynch syndrome (151). First, the majority of the colorectal cancers, 60–70%, occur in the proximal colon, and tend to be detected at an earlier stage. Approximately 37% have a poorly differentiated appearance, mucinous cancers are more common, excess mucin occurs in about one-third of cancers, and signet ring cells are more commonly seen (57,152). Flow cytometric studies indicate that 90% of these tumors are diploid or near-diploid (153), and there is less CIN in tumors that demonstrate the features seen in Lynch syndrome tumors (54,55). Lynch syndrome predisposes to multiple synchronous (18%) and metachronous (45% by 10 years if not treated with subtotal colectomy) cancers, indicating that these patients are at substantial risk for multicentric disease (154).

**70.3.2.5 Colonic Polyps in Lynch Syndrome.** Colonic polyposis, such as that seen in FAP, is not seen in Lynch syndrome. However, adenomatous polyps are more common in individuals at risk for Lynch syndrome. Adenomas can be found in 30% of the first-degree relatives of Lynch syndrome patients with at least one adenoma present at a mean age of 44 years, and 20% have multiple adenomas. Furthermore, like the cancers, the adenomas have a predilection for the proximal colon (155). Moreover, the adenomatous polyps tend to be larger and to be detected at more advanced pathologic stages, suggesting that they may grow faster and intrinsically be more aggressive than sporadic adenomas. Because of the shorter time in the evolution of an adenoma to carcinoma, seeing more than three adenomatous polyps before age 30, or more than six before age 50, suggests some diagnosis other than Lynch Syndrome (156).

**70.3.2.6 Prognosis in Lynch Syndrome.** Patients who develop colorectal cancers in the setting of Lynch syndrome have a significantly better prognosis than might be expected when compared with stage-matched controls. This is true for patients who meet the clinical criteria for Lynch syndrome (157), families with germline mutations in the *hMLH1* gene (158), and in young patients with MSI colon cancers, which would include many Lynch syndrome patients, and others who are not well characterized (159). Patients with Lynch syndrome-related colorectal cancers present with lower-stage disease and are less likely to present with distant metastases (160), and young patients whose tumors have MSI have a relative hazard ratio for death of 0.42 compared to tumors without MSI (159).

The penetrance for cancer of this disease is clearly less than 100%, and germline mutations in the DNA MMR genes are often found in families that do not meet the initial Amsterdam criteria (161). The tumor spectrum in Lynch syndrome was estimated from one study of 315 individuals at risk for the disease. In these families, 63% of the tumors were colorectal, 8% were endometrial, 6% were gastric, 4% were in the pancreaticobiliary tree, and other organs were occasionally affected (162).

**70.3.2.7 Clinical Variation in Lynch Syndrome.** It was suggested in 1984 that there may be two variants, initially termed Lynch syndromes I and II, in which type I was colon cancer specific, and type II had more extracolonic cancers (163). Although such familial phenotypes occur, disease variation is mainly linked to the DNA MMR genes that give rise to the disease. Germline mutations in the minor DNA MMR genes (*hMSH6* and *hPMS2*) give rise to an attenuated phenotype. Specifically, germline mutations in the *hMSH6* gene are associated with later onset of colon cancers (median age for cancer being in the sixties), with incomplete penetrance, and an increase in the relative impact of endometrial cancers in the women of these families. In addition, 86% of the tumors are MSI-H and 14% are MSI-L, and the latter may be missed, depending on the panel of microsatellites used to screen for this mutational signature (164). Lynch syndrome caused by *hPMS2* mutations is more complicated, but the penetrance appears to be less than that associated with the other Lynch Syndrome genes. When isolated loss of *hPMS2* expression was found in a large group of colorectal cancers, this was associated with early onset of disease, but not with a striking family history of cancer (165).

**70.3.2.8 Muir–Torre Syndrome.** Another variation of Lynch syndrome has been called the Muir–Torre syndrome, which is typical Lynch syndrome complicated by benign or malignant sebaceous tumors and keratoacanthomas of the skin. MSI has been found in the cutaneous and internal malignancies of Muir–Torre syndrome (166). Furthermore, several families have been linked to the *hMSH2* and *hMLH1* loci in this disease, which clearly identifies it as a member of the Lynch syndrome family of diseases (167,168). The presence of multiple sebaceous neoplasms (including sebaceous adenomas, sebaceous epitheliomas, and sebaceous carcinomas), or keratoacanthomas in any patient, strongly suggests the diagnosis of Muir–Torre syndrome.

**70.3.2.9 Diagnosis of Lynch Syndrome.** Traditionally, the diagnosis of Lynch syndrome is made on the basis of family history, with an emphasis on early onset of proximal colon cancers clustering in a family. In 1991, diagnostic criteria known as the Amsterdam criteria (169) were developed by an international collaborative group. They required (1) three or more family members with histologically verified colorectal cancer, one of whom is a first-degree relative of the other two; (2) colorectal cancer involving at least two successive generations; (3) one or more colorectal cancer cases diagnosed before age

50; and (4) FAP is excluded. The original Amsterdam criteria were useful to standardize collaborative studies, but were too restrictive for clinical use as they failed to acknowledge the contribution of endometrial and other extracolonic cancers, and made it relatively unlikely that a small family would fit the criteria. The modified Amsterdam criteria (170) and the revised Bethesda criteria (124) have been developed to improve our ability to diagnose this disease (Table 70-5), and these acknowledge the presence of tumors in nonintestinal organs in this disease (most prominently endometrial cancer), and the use of molecular diagnostics on tumor tissue.

The genetic diagnosis of Lynch syndrome has intrinsic problems depending on the gene involved. Mutations in *hMSH2* are frequently premature stop codons, which are almost always pathogenic. However, a substantial proportion of *hMSH2* mutations are caused by large deletions that are not detected by DNA sequencing, and require techniques that detect whether there are one or two alleles in the exon being sequenced (171). Deletions are a common problem with *hMSH2* because the 5' end of this gene is located in a cluster of *Alu* sequences, which are prone to recombination with excision of the DNA between the hybridized sequences. This genetic alteration is present in 20–25% of cases in which the germline mutation is suspected in *hMSH2*, but none is found (172). Curiously, *Alu*-mediated losses of the termination codon of the

*EPCAM* gene, which is immediately upstream of *hMSH2*, leads to methylation of the promoter of *hMSH2* in the tissues in which *EPCAM* is expressed, and produces a syndrome that mimics Lynch syndrome-*MSH2* type (173).

Many institutions will initiate their evaluation for Lynch syndrome using immunohistochemical staining of the tumor tissue for the two pairs of DNA MMR proteins, *hMSH2* plus *hMSH6*, and *hMLH1* plus *hPMS2*. The absence of staining of either *hMSH2* or *hMLH1* is accompanied by the loss of staining for *hMSH6* and *hPMS2*, respectively, as these are their heterodimeric partners.

The most common DNA MMR abnormality at immunohistochemistry in a group of unselected colorectal cancers will be the paired losses of *hMLH1* and *hPMS2*, which will most commonly reflect biallelic methylation of the promoters of *hMLH1*; this can be confirmed by an assay for promoter methylation or *BRAF* mutation (59). In the absence of methylation-mediated silencing, one needs to determine whether there is a germline mutation in the *hMLH1* gene. However, the interpretation of mutations at the *hMLH1* locus can be hazardous, as many are missense mutations, and it is not always apparent a priori whether such a mutation will abrogate function (174). Functional studies are cumbersome, but may be the only way to determine whether some of these mutations are truly pathogenic (175). Moreover, it is possible to find instances in which the germline mutation in *hMLH1* leads to MSI and isolated loss of *hPMS2* staining at immunohistochemistry. This scenario can be caused by a missense mutation in the *hMLH1* gene that abrogates the ability of the *hMLH1* protein to interact with the *hPMS2* protein. There have been instances of soma-wide methylation of *hMLH1*, with methylation present in blood, skin and gut epithelium, and this will mimic Lynch syndrome-*MLH1* type (176). Inheritance of this epigenetic germline alteration has also been reported, although the mechanism responsible for this is not known (177).

Germline mutations in the *hMSH6* gene cause a modified form of the disease. Families with *hMSH6* mutations have a delayed-onset form of Lynch syndrome in which the median onset of disease is 10–20 years later, colorectal cancer may be less prominent, and endometrial cancers become a more important clinical feature (108). Of particular importance, when these individuals reach their 70s and 80s, they have accumulated the same total prevalence of cancer as occurs in families with germline mutations in *hMSH2* or *hMLH1*, but the tumors appear later, and there is the very high incidence of endometrial cancer (164). Perhaps more importantly, 8% of familial clusters of colorectal cancer in which the Amsterdam criteria were not met were associated with germline mutations in *hMSH6* (107). Between 16 and 21% of colorectal cancer patients under age 50 who have no more than one first-degree relative with colorectal cancer have Lynch syndrome, which is over-represented with alterations in *hMSH6* and *hPMS2* (178,179).

**TABLE 70-5 Increased Suspicion for Lynch Syndrome: Clinical Criteria**

<p>A. Modified Amsterdam Criteria (for Lynch Syndrome) (Vasen et al., 1999)</p> <ol style="list-style-type: none"> <li>(1) Three relatives with pathologically verified colorectal cancer, or other Lynch syndrome-associated cancer<sup>a</sup></li> <li>(2) One patient is a first-degree relative of the other two</li> <li>(3) At least two successive generations are affected</li> <li>(4) FAP is excluded</li> <li>(5) One cancer has occurred &lt;50 years</li> </ol>
<p>B. Revised Bethesda criteria (to prompt MSI testing in colorectal cancer) (Umar et al., 2004)</p> <ol style="list-style-type: none"> <li>(1) Colorectal cancer in a patient &lt;50 years old</li> <li>(2) Multiple synchronous or metachronous Lynch syndrome-associated cancers<sup>a</sup></li> <li>(3) Colorectal cancer with the "MSI-H" histology<sup>b</sup> in a patient &lt;60 years old</li> <li>(4) Colorectal cancer in ≥1 first-degree relatives with a Lynch syndrome-related tumor,<sup>a</sup> in which one of the cancers is diagnosed in a person &lt;50 years old</li> <li>(5) Colorectal cancer diagnosed in ≥2 first- or second-degree relatives with a Lynch syndrome-related tumor,<sup>a</sup> regardless of age</li> </ol>

<sup>a</sup>Adenocarcinoma of the colon, rectum, endometrium, stomach, ovary, pancreas, small bowel, ureter or renal pelvis, biliary tract; also, glioblastoma multiforme of the CNS or tumors of the Muir-Torre syndrome spectrum (sebaceous neoplasms and keratoacanthomas).

<sup>b</sup>The presence of tumor-infiltrating lymphocytes, Crohn-like lymphocytic reaction, mucinous/signet ring differentiation, or medullary growth pattern.

Finally, it has been estimated that some proportion of Lynch syndrome is due to germline mutations in the *hPMS2* gene (116,180). This conclusion can be reached by finding isolated loss of hPMS2 staining at immunohistochemistry, and excluding a germline mutation in the *hMLH1* gene (116). However, detection of the germline mutation in *hPMS2* is very difficult because of the presence of many pseudogenes of hPMS2 in the human genome, which provides extra wild-type copies of the *hPMS2* sequence, which obfuscate the DNA sequencing results (181). Lynch syndrome caused by germline mutations in *hPMS2* may be attenuated as it is in the case of *hMSH6*, but too few families have been reported to be certain of the phenotype in this circumstance, and it is likely that many families have been overlooked because of the diagnostic challenges.

Genetic testing for Lynch syndrome using DNA sequencing is still imperfect. First, there are multiple genes that contribute to the syndrome, and for each gene the mutations are scattered over multiple exons. Direct sequencing strategies will not detect some disease-causing mutations, such as genomic deletions, which are often not detectable using exon-by-exon sequencing, as mentioned above for *hMSH2* (171). Germline mutations can be found in half (or fewer) of familial colon cancer clusters, regardless of the means of genetic testing (161). It is reasonable to consider testing for MSI in any colon cancer patient under age 70 (117), and then to pursue specific DNA MMR genes when this is positive. Two studies of cohorts of colorectal cancer patients who do not have more than one first-degree relative with colorectal cancer have shown that 16–20% of these patients have cryptic, unsuspected Lynch syndrome (178,179).

Biallelic germline mutations have been reported for all four Lynch syndrome genes. This causes a virulent, early-onset tumor diathesis beginning in childhood including hematological malignancies, and colorectal cancers before age 20. The patients may have café-au-lait spots, and be misdiagnosed as neurofibromatosis (182).

**70.3.2.10 Management of Lynch Syndrome.** Once a diagnosis of Lynch syndrome is definite, the patient may opt for one of two management options. Colonoscopic surveillance every 2–3 years has been shown to detect early-stage tumors and significantly reduce mortality from colon cancer (183). A consensus developed by several groups has recommended surveillance every 1–2 years, beginning at age 25 (117,184). The ordinary surveillance interval of 5 years used for patients with sporadic neoplasms is not adequate because of the rapid progression of adenoma to carcinoma in this setting (156,185). Some patients may prefer to avoid a large number of colonoscopic procedures and choose a prophylactic colectomy. Such patients do not require a total proctocolectomy, as the distal colon is relatively spared in this disease and can be managed with sigmoidoscopy annually.

If surgery is performed in Lynch syndrome, a subtotal colectomy is recommended whether the tumor is

in the proximal or the distal colon. It is not possible to make recommendations regarding the use of chemotherapy, or postoperative radiation (for rectal cancers). In vitro data suggest that these tumors will be relatively resistant to a wide range of chemotherapeutic agents (186,187), but so far there are no prospective clinical trials on which to base therapeutic decisions. The prognosis is significantly better for MSI-H tumors than for non-MSI-H tumors, in aggregate, or when matched for stage (159). A large, multicenter trial in which colorectal cancer patients were randomized to receive 5-fluorouracil (5-FU)-based chemotherapy was retrospectively analyzed for outcome based on the MSI status. No benefit was seen for adjuvant chemotherapy in patients whose colorectal cancer was MSI-H (but was observed for MSS tumors), and there was a suggestion that this treatment doubled the risk of death in such patients (188). The absence of benefit for adjuvant 5-FU-based chemotherapy has been confirmed in multiple studies (reviewed in (189)). Pooled analyses of multiple trials suggest that this is not a simple issue. Adjuvant chemotherapy may reduce distant metastatic recurrences in stage III MMR-deficient colorectal cancer patients, but result in an increase in intra-abdominal recurrences, and show no benefit in stage II tumors (190). One should be cautious when considering the use of adjuvant chemotherapy in patients with Lynch syndrome until data demonstrate that benefit will be derived from this treatment in each of these clinical subsets of patients.

**70.3.2.11 Management of Patients with a Family History of Colon Cancer.** Approximately 5% of the North American population will develop colorectal cancer. Depending on family size, therefore, many patients will seek advice from a physician when a family member develops an intestinal tumor. To advise such patients properly, it is essential to obtain a careful family history, document the tumors where possible, and inquire about the age of tumor onset and the multiplicity of tumors in the relatives. More tumors and earlier age of onset in a relative increase an individual's risk for cancer.

As mentioned earlier, colorectal cancer is common, so both positive and negative information will be important. In a large family in which many members have lived into, say, their eighties, and no tumors have developed, the risk for colorectal cancer is probably less than normal. In a small family even one colon cancer may be important, especially if it occurs in a young first-degree relative. At one end of the spectrum, patients in Lynch syndrome families have a 50% risk of inheriting a susceptibility gene, and the penetrance for tumor development may be as high as 80–90%. The Amsterdam criteria for Lynch syndrome require that three family members have colorectal cancer, more than one generation be involved, and at least one individual be affected before 50 years of age. More ambiguous degrees of a positive family history result in an estimated risk that would fall between 5 and 50%, and the involvement of

a genetic factor might also decrease the age at which a tumor may develop.

It has been estimated that the age-adjusted RR of colorectal cancer for men and women with any affected first-degree relative is 1.72 (95% confidence interval, 1.34–2.19), and the RR when there are two or more affected first-degree relatives is 2.75 (95% confidence interval, 1.34–5.63) (191). Therefore, when a patient has one first-degree relative with colorectal cancer, it should alert the clinician to the need for some type of screening. The presence of two or three affected family members, particularly when one or more cancers occur in younger patients (i.e. individuals less than 50–55 years), increases the suspicion of Lynch syndrome. Positive family histories for cancer also confer an earlier age of onset of the disease among the relatives (192).
